**Studies of J/ψ production at forward rapidity in Pb–Pb collisions at
 $\sqrt{s_{NN}} = 5.02$ TeV**

ALICE Collaboration*

Abstract

The inclusive J/ψ production in Pb–Pb collisions at the center-of-mass energy per nucleon pair $\sqrt{s_{NN}} = 5.02$ TeV, measured with the ALICE detector at the CERN LHC, is reported. The J/ψ meson is reconstructed via the dimuon decay channel at forward rapidity ($2.5 < y < 4$) down to zero transverse momentum. The suppression of the J/ψ yield in Pb–Pb collisions with respect to binary-scaled pp collisions is quantified by the nuclear modification factor (R_{AA}). The R_{AA} at $\sqrt{s_{NN}} = 5.02$ TeV is presented and compared with previous measurements at $\sqrt{s_{NN}} = 2.76$ TeV as a function of the centrality of the collision, and of the J/ψ transverse momentum and rapidity. The inclusive J/ψ R_{AA} shows a suppression increasing toward higher p_T , with a steeper dependence for central collisions. The modification of the J/ψ average p_T and p_T^2 is also studied. Comparisons with the results of models based on a transport equation and on statistical hadronization are also carried out.

arXiv:1909.03158v1 [nucl-ex] 7 Sep 2019

1 Introduction

The study of ultra-relativistic heavy-ion collisions aims to investigate the properties of strongly-interacting matter at high temperature and energy density. Lattice Quantum Chromodynamics calculations predict that a deconfined state of partonic matter, the so-called Quark–Gluon Plasma (QGP), can be created in such collisions [1–3]. Among the many possible probes to study this phase of matter, heavy quarks are particularly interesting as they are expected to be produced in the initial stage of the collisions, by hard partonic scatterings, and to experience the full evolution of the system. In particular, it was predicted that bound states of charm (c) and anti-charm (\bar{c}) quarks (known as charmonia) should be suppressed due to the color-screening mechanism [4]. The suppression probabilities of the quarkonium ($c\bar{c}$ or $b\bar{b}$) states in the QGP depend on their binding energies and the medium temperature. Therefore, the measurement of the relative production rates of the quarkonium states should give indications on the temperature of the system [5]. Among the different charmonium states, the study of the ground state with quantum numbers $J^{PC} = 1^{--}$ (J/ψ) is comparatively more accessible due to its larger abundance and to the relatively large branching ratio to dileptons, and has led to several important results.

Over the past decades, the J/ψ production in heavy-ion collisions was measured at the SPS, RHIC and the LHC, covering a wide range of center-of-mass energies per nucleon pair ($\sqrt{s_{\text{NN}}}$) from about 17 GeV to 5.02 TeV. A suppression of the J/ψ production yield in nucleus–nucleus (AA) relative to that expected from measurements in proton–proton (pp) collisions was observed at the SPS at $\sqrt{s_{\text{NN}}} = 17$ GeV [6, 7], at RHIC up to $\sqrt{s_{\text{NN}}} = 0.2$ TeV [8–11] and at the LHC at $\sqrt{s_{\text{NN}}} = 2.76$ TeV [12–16] and 5.02 TeV [17, 18]. The suppression is evaluated through the calculation of the nuclear modification factor (R_{AA}), corresponding to the ratio of the production yields in AA and the cross section in pp collisions, normalised by the nuclear overlap function $\langle T_{\text{AA}} \rangle$ [19]. The observed suppression does not increase with increasing collision energy as expected in the color-screening picture considering the increasing temperature of the formed QGP. This observation is naturally explained by a further production mechanism known as regeneration, in which abundantly produced $c\bar{c}$ pairs recombine into J/ψ [20, 21]. The contribution of the regeneration to J/ψ production has to increase with the density of $c\bar{c}$ pairs and consequently with the collision energy. It is worth noting that the regeneration contribution should favour low transverse momentum (p_{T}) J/ψ, as the bulk of charm quarks are produced at small momenta [20, 21]. The regeneration scenario was further supported by the measurement of a positive J/ψ elliptic flow (v_2) [22, 23] which, at low p_{T} , can be acquired via charm-quark recombination [24, 25]. It is important to note that in addition to the effects discussed above, related to the production of a high energy-density medium, the so-called cold-nuclear-matter effects may also have a sizeable influence on the charmonium yields. In particular, the modification of the parton distribution functions in the nucleus (e.g. nuclear shadowing [26, 27]) may modify the initial yields of charm quarks and has to be taken into account in the interpretation of the results. Quantitative estimates of these effects are carried out via the study of proton–nucleus collisions [28–33]. Finally, a quantitative interpretation of the results requires taking into account that the observed J/ψ are produced either promptly, i.e. as direct J/ψ or via decay of higher-mass charmonium states (χ_c , $\psi(2S)$), or non-promptly through the weak decay of hadrons containing a beauty (b) quark [34].

For a better assessment of the suppression-regeneration scenario, extensive studies of the centrality, p_{T} and rapidity dependence of the J/ψ nuclear modification factor have to be carried out. The first ALICE measurement of the inclusive (sum of prompt and non-prompt sources) J/ψ production at $\sqrt{s_{\text{NN}}} = 5.02$ TeV at forward rapidity [17] has shown a hint for an increase of R_{AA} with respect to the $\sqrt{s_{\text{NN}}} = 2.76$ TeV results in the region $2 < p_{\text{T}} < 6$ GeV/c, while the results were consistent elsewhere.

In this paper, we complement the results obtained in Ref. [17]. The J/ψ R_{AA} is simultaneously obtained in different collision centrality classes and p_{T} or rapidity intervals. In addition, to further assess the kinematic region of influence of the J/ψ regeneration mechanism, results on the J/ψ average p_{T} and p_{T}^2 as a function of centrality are presented.

The paper is organized as follows: Sec. 2 is dedicated to the description of the ALICE detector systems used in this analysis. The analysis procedure is briefly explained and a summary of the systematic uncertainties is also given in Sec. 3. Results are presented and compared to available measurements at $\sqrt{s_{\text{NN}}} = 2.76$ TeV and model calculations in Sec. 4.

2 Apparatus and data samples

The ALICE detector and its performance are extensively described in Ref. [35] and [36], respectively. J/ψ mesons are reconstructed in the muon spectrometer (covering the pseudo-rapidity interval $-4 < \eta < -2.5$ ¹) via their dimuon decay channel down to zero p_{T} . The muon spectrometer consists of a 4.1 m (10 interaction lengths, λ_{int}) thick front absorber which is used to filter out hadrons coming from the interaction point (IP), followed by tracking (MCH) and triggering (MTR) systems. Each of the five tracking stations is composed of two planes of Cathode Pad Chambers. The third tracking station is located inside a dipole magnet with a field integral of 3 Tm. A 1.2 m ($7.2\lambda_{\text{int}}$) thick iron wall, which absorbs secondary hadrons escaping from the front absorber and low-momentum muons produced predominantly from π and K decays, is located between the tracking system and the trigger stations. Each of the two trigger stations consists of two planes of Resistive Plate Chambers. Finally, a small-angle conical absorber around the beam-pipe protects the spectrometer from secondary particles produced by interactions of large- η primary particles with the beam-pipe.

The other detectors used in this analysis are the Silicon Pixel Detector (SPD), the V0 scintillator detectors, the Cherenkov detectors T0 and the Zero Degree Calorimeters (ZDC). The SPD [37] provides the coordinates of the primary vertex of the collision, and consists of two cylindrical layers covering $|\eta| < 2$ (inner layer) and $|\eta| < 1.4$ (outer layer). The V0 [38], composed of two arrays of 32 scintillator tiles each, and located on both sides of the IP, covers $2.8 < \eta < 5.1$ (V0A) and $-3.7 < \eta < -1.7$ (V0C), and is used as a trigger detector, for the centrality determination and to remove beam-induced background. It is also used for the measurement of the luminosity along with the T0 detector [39], which consists of two quartz Cherenkov counters, located on each side of the IP and covering the pseudo-rapidity intervals $-3.3 < \eta < -3$ and $4.6 < \eta < 4.9$. The ZDCs, located on either side of the IP at ± 114 m along the beam axis, detect spectator nucleons emitted at zero degrees with respect to the LHC beam axis, and are used to reject electromagnetic Pb–Pb interactions [40].

The centrality determination and the evaluation of the average number of participant nucleons in the collision $\langle N_{\text{part}} \rangle$ for each centrality class is based on a Glauber model fit to the V0 signal amplitude distribution as described in Ref. [41, 42]. The events are classified in centrality classes corresponding to percentiles of the nuclear hadronic cross section. In this analysis, events corresponding to the most central 90% of the inelastic cross section were selected. For these events the minimum bias (MB) trigger is fully efficient and the residual contamination from electromagnetic processes is negligible. The MB trigger is defined by a coincidence of the signals from both sides of the V0 detector.

The analysis presented here is based on dimuon-triggered events which require, in addition to the MB condition, the detection of two Unlike-Sign (US) tracks in the triggering system of the muon spectrometer. The muon trigger selects muon candidates having a transverse momentum larger than a given threshold which corresponds to the value for which the trigger efficiency reaches 50%. In Pb–Pb collisions the p_{T} threshold is ≈ 1 GeV/c with the single-muon trigger efficiency reaching a plateau value of 98% at ≈ 2.5 GeV/c [43].

The current analysis exploits the data samples of Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 5.02$ TeV collected during 2015. This corresponds to an integrated luminosity $L_{\text{int}}^{\text{PbPb}} \approx 225 \mu\text{b}^{-1}$.

¹In the ALICE reference frame, the muon spectrometer covers a negative η interval and consequently negative y values. We have chosen to present our results with a positive y notation.

3 Data analysis

Below, the definitions of the measured observables are given, followed by a presentation of the main analysis steps and a discussion of the systematic uncertainties. For a centrality class i , the double-differential J/ψ invariant yield $Y_{\text{J}/\psi}^i$ is defined as

$$\frac{d^2 Y_{\text{J}/\psi}^i}{dy dp_T} = \frac{N_{\text{J}/\psi}^i(p_T, y)}{\text{BR}_{\text{J}/\psi \rightarrow \mu^+ \mu^-} \cdot (A \times \epsilon)^i(p_T, y) \cdot \Delta p_T \cdot \Delta y \cdot N_{\text{MB}}^i}, \quad (1)$$

where $N_{\text{J}/\psi}^i(p_T, y)$ is the number of J/ψ for a given p_T and y interval, $\text{BR}_{\text{J}/\psi \rightarrow \mu^+ \mu^-} = (5.96 \pm 0.03)\%$ is the branching ratio of the dimuon decay channel [44], $(A \times \epsilon)^i(p_T, y)$ is the product of the detector acceptance and the reconstruction efficiency for that p_T and y interval, and N_{MB}^i is the equivalent number of minimum-bias events. It is obtained as the product of the number of dimuon-triggered events times the inverse of the probability of having a dimuon trigger in a MB event (F^i). The F^i values correspond to those quoted in Ref. [17]. For the centrality integrated sample, the value of the normalization factor is $F^{0-90\%} = 11.84 \pm 0.06$. The quoted uncertainty is systematic and corresponds to the difference between the results obtained with two methods, either by calculating the ratio of the counting rates of the two triggers, or by applying the dimuon trigger condition in the analysis of MB events.

The nuclear modification factor R_{AA} is given by

$$R_{\text{AA}}^i(p_T, y) = \frac{d^2 Y_{\text{J}/\psi}^i / dy dp_T}{\langle T_{\text{AA}} \rangle^i \cdot d^2 \sigma_{\text{J}/\psi}^{\text{pp}} / dy dp_T}, \quad (2)$$

where $\langle T_{\text{AA}} \rangle^i$ is the average of the nuclear-overlap function [19]. The values of $\langle T_{\text{AA}} \rangle^i$ in different centrality classes were obtained using a Glauber calculation [42, 45, 46]. The systematic uncertainty on the $\langle T_{\text{AA}} \rangle^i$ calculation, which ranges from 1% in the most central class to 3% in the most peripheral one, was determined by varying the density parameters of the Pb nucleus and the nucleon–nucleon inelastic cross section within their uncertainties. The systematic uncertainty on the definition of the centrality intervals is evaluated by varying by $\pm 0.5\%$ the fraction (90%) of the hadronic cross section selected with the chosen minimal cut on the V0 signal amplitude, and redefining accordingly the centrality intervals, following the approach detailed in Ref. [17]. Values of the J/ψ cross section in pp collisions ($d^2 \sigma_{\text{J}/\psi}^{\text{pp}} / dy dp_T$) at $\sqrt{s} = 5.02$ TeV were already reported in Ref. [17, 47]. Here, following the same analysis procedure as detailed in those papers, the cross section was evaluated in four p_T intervals (0.3–2, 2–5, 5–8, and 8–12 GeV/c) for the interval $2.5 < y < 4$ and three y intervals (2.5–3, 3–3.5, and 3.5–4) for the interval $p_T < 12$ GeV/c. The integrated luminosity of the pp sample is $L_{\text{int}}^{\text{pp}} = (106.3 \pm 2.2) \text{ nb}^{-1}$ [48].

The J/ψ candidates were formed by combining US muons reconstructed within the geometrical acceptance of the muon spectrometer using the tracking algorithm described in Ref. [49]. The selection criteria applied to both single muons and dimuons are similar to the ones used in Ref. [14, 17], requiring a match between tracks reconstructed in the tracking system and track segments in the muon trigger system.

The signal extraction was performed over various centrality, p_T and y intervals using two methods. In the first one, the US dimuon invariant mass distributions were fitted with the sum of a signal and a background function. In the second one, the combinatorial background (dominant in central Pb–Pb collisions) was first estimated using an event-mixing technique, and then subtracted from the raw invariant mass distribution. Finally, the resulting distributions were fitted with the sum of a signal and a residual background component.

The signal component of the fitting function is either an extended Crystal Ball (CB2) function or a pseudo-Gaussian with a mass-dependent width [50]. For both functions, the position of the J/ψ pole

mass, as well as the width of the resonance, are free parameters of the fits, while the non-Gaussian tail parameters were fixed. Two sets of tail parameters were obtained from Monte Carlo (MC) simulations using different particle transport codes (GEANT3 [51] and GEANT4 [52]) to account for the sensitivity of these parameters to the description of the detector materials. In addition, another set of CB2 tail parameters was extracted from the pp collisions at $\sqrt{s} = 13$ TeV data sample [47], the sample with the largest significance of the J/ ψ signal. Finally, the contribution of the $\psi(2S)$ signal was also taken into account in the fits, using the same signal functions as for the J/ ψ , with mass and width tied to those of the J/ ψ [53].

The background was parametrized either as a pseudo-Gaussian with a width quadratically dependent on the mass or as a ratio of a 2nd to 3rd order polynomial. When using the event-mixing technique, the continuum component of the correlated background remaining in the US dimuon distributions after the background subtraction was parametrized using the sum of two exponential functions. Examples of fits to the US dimuon invariant mass distributions, without and with subtraction of mixed-event background, are shown in Fig. 1 for different centrality classes and p_{T} intervals. For each centrality class, p_{T} and y interval, the number of J/ ψ and the statistical uncertainty are given by the average of the results from the considered fit configurations obtained by varying the signal and background functions, the tail parameters and the invariant mass fit range ([2.2,4.5] or [2.4,4.7] GeV/ c^2). The systematic uncertainty is defined, for each centrality, p_{T} and y interval, as the RMS of the various fit results. It varies between 1.5% and 3.6% as a function of centrality or p_{T} and between 1.5% and 5% as a function of y .

Fig. 1: Example of fits to the US dimuon invariant mass distributions in Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 5.02$ TeV in different centrality classes and p_{T} intervals. The left (right) panels show the distributions before (after) background subtraction with the event-mixing technique. Dashed gray curves correspond to background functions, red curves to the signal functions and blue curves to the sum of the signal and background functions.

The $J/\psi A \times \varepsilon$ was obtained using MC simulations, where the p_{T} and y distributions for the generated J/ψ were matched to the ones extracted from data using an iterative procedure as done in Ref. [29]. Unpolarized J/ψ production was assumed [54, 55]. The misalignment of the detection elements as well as the time-dependent status of each electronic channel during the data taking period were taken into account in the simulation. Generated $J/\psi \rightarrow \mu^+ \mu^-$ signals were embedded into real minimum bias events in order to properly reproduce the effect of detector occupancy and its variation from one centrality class to another, and reconstructed as for real events. A relative decrease by $\sim 14\%$ of $A \times \varepsilon$ was observed in the most central Pb–Pb collisions with respect to the most peripheral ones.

The following sources of systematic uncertainty on $A \times \varepsilon$ were considered: (i) the parametrization of the input p_{T} and y shapes, (ii) the uncertainty on the tracking efficiency in the muon tracking chambers, (iii) the uncertainty on the MTR efficiency and (iv) the matching between tracks reconstructed in the tracking and triggering systems.

For the parametrization of the MC input distributions, two sources of systematic uncertainty were considered: the effect of the finite data sample used to parametrize these distributions and the correlations between p_{T} and y (more explicitly, the fact that the p_{T} distribution of the J/ψ varies within the rapidity interval in which it is measured). The former turns out to be negligible. For the latter, different MC simulations were performed by varying the input p_{T} and y distributions within limits that correspond to this effect and re-calculating the $A \times \varepsilon$ in each case as done in Ref. [47]. The uncertainties on the tracking efficiency in the MCH, trigger efficiency in the MTR, and on the matching efficiency between MTR and MCH tracks were evaluated by comparing the efficiencies obtained in data and MC at the single muon level and propagating the observed differences to the J/ψ candidates, as done in Ref. [56].

In each centrality, p_{T} and y interval, the total systematic uncertainty on the yield and R_{AA} is determined as the quadratic sum of the uncertainties from the different sources listed in Table 1. Correlations of various uncertainties vs centrality, p_{T} or y are also reported. The values in the last row correspond to the sum of the statistical and systematic uncertainties on the pp reference.

Table 1: Summary of systematic uncertainties, in percentage, on the yield and R_{AA} in Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 5.02$ TeV. Values with an asterisk correspond to the systematic uncertainties correlated as a function of the given variable.

| Sources | vs centrality | vs p_{T} | vs y |
|--|---------------|-------------------|------------------|
| Signal extraction | 1.5–3.6 | 1.5–3.6 | 1.5–5.0 |
| MC input | 2* | 2–3 | 0.5–2.5 |

4 Results

4.1 Nuclear modification factor

This section summarizes the results for the inclusive J/ψ R_{AA} at forward rapidity in Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 5.02$ TeV as a function of:

- rapidity and transverse momentum, integrated over the centrality (class 0–90%);
- rapidity and transverse momentum, for the centrality classes 0–20%, 20–40% and 40–90%;
- centrality, in four transverse momentum intervals and in three rapidity intervals.

When possible, the ratio between the results of this analysis and the measurements in Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 2.76$ TeV [14], in the same kinematic interval, is computed. Only the uncertainty related to the $\langle T_{\text{AA}} \rangle$ cancels out in the ratio, as discussed in Ref. [17]. Following the same approach as in Ref. [14, 17], an estimate of the R_{AA} of prompt J/ψ was determined by making conservative assumptions on the size of the non-prompt R_{AA} . The relation between the inclusive (R_{AA}), prompt ($R_{\text{AA}}^{\text{prompt}}$) and non-prompt ($R_{\text{AA}}^{\text{non-prompt}}$) nuclear modification factors can be expressed as:

$$R_{\text{AA}}^{\text{prompt}} = \frac{R_{\text{AA}} - F_{\text{B}} \cdot R_{\text{AA}}^{\text{non-prompt}}}{1 - F_{\text{B}}}, \quad (3)$$

where F_{B} is the fraction of non-prompt to inclusive J/ψ in pp collisions. This quantity is evaluated at $\sqrt{s} = 5.02$ TeV by interpolating in energy the corresponding LHCb cross-section measurements in pp collisions at $\sqrt{s} = 2.76$ and 7 TeV [57–59]. The limits on $R_{\text{AA}}^{\text{prompt}}$ correspond to the two extreme hypotheses of total non-prompt J/ψ suppression ($R_{\text{AA}}^{\text{non-prompt}} = 0$) and absence of suppression ($R_{\text{AA}}^{\text{non-prompt}} = 1$). The effect is small at moderate transverse momentum ($\lesssim 10\%$ for $p_{\text{T}} \lesssim 5$ GeV/c) and then increases at higher p_{T} . Numerical values for the limits on $R_{\text{AA}}^{\text{prompt}}$ can be found in the HepData record associated to this paper. Another effect which may influence the interpretation of the inclusive J/ψ results is the presence of an excess at very low p_{T} , observed at $\sqrt{s_{\text{NN}}} = 2.76$ TeV [60] and related to J/ψ photo-production [61]. This source was shown to be significant with respect to hadronic production for peripheral Pb–Pb collisions and has a strong influence on the measured R_{AA} values. For this reason, the region $p_{\text{T}} < 0.3$ GeV/c was excluded when dealing with peripheral collisions. The remaining contribution of this source was evaluated following the procedure detailed in Ref. [14] and the maximum effect on R_{AA} is explicitly shown in the following figures by use of bracket symbols. The upper limit bracket corresponds to the assumption of no contribution from photo-produced J/ψ, while the lower one corresponds to the hypothesis that all the J/ψ with $p_{\text{T}} < 300$ MeV/c are photo-produced.

4.1.1 Centrality-integrated R_{AA} as a function of y and p_{T}

Figures 2 and 3 show the inclusive J/ψ nuclear modification factor as a function of transverse momentum and rapidity, integrated over the centrality class 0–90%. The results are compared with those obtained at $\sqrt{s_{\text{NN}}} = 2.76$ TeV [14] and with the results of the calculation of a transport model [24, 62]. A significant increase of R_{AA} is visible with decreasing p_{T} , which was already observed for the most central events (0–20%) and reported in Ref. [17]. Within uncertainties, the results are compatible with those obtained, in a more restricted p_{T} interval, at the lower LHC energy, with a possible hint (1.2σ) of a weaker suppression in the region $2 < p_{\text{T}} < 6$ GeV/c. The transport model calculations are in qualitative agreement with the data. In this model, a competition between suppression and regeneration of charmonia is assumed, choosing a $c\bar{c}$ production cross section $d\sigma_{c\bar{c}}/dy = 0.57$ mb and $d\sigma_{\text{J}/\psi}^{\text{pp}}/dy = 3.35$ μb for $2.5 < y < 4$. The latter value is $\sim 10\%$ smaller than our measurement of the same quantity [17]. The model also

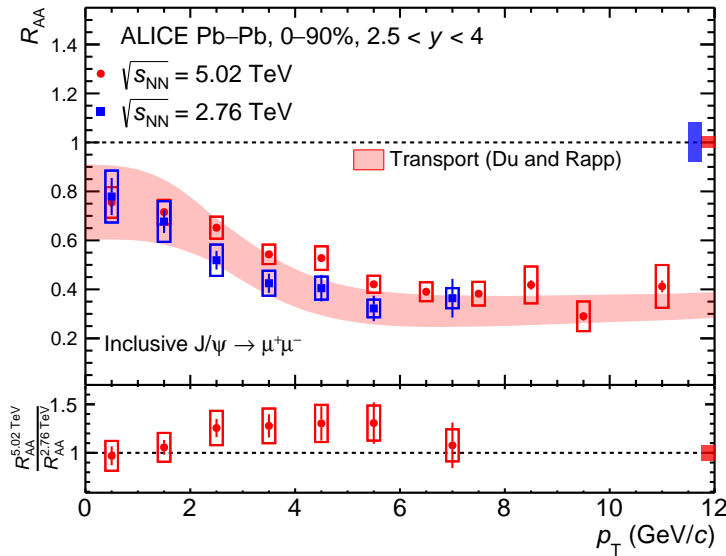

Fig. 2: Inclusive J/ψ nuclear modification factor as a function of p_T for Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 5.02$ TeV in the 0–90% centrality class. The vertical error bars represent statistical uncertainties, the boxes around the points uncorrelated systematic uncertainties, while the correlated uncertainty is shown as a filled box around $R_{\text{AA}} = 1$. The corresponding measurements in Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 2.76$ TeV [14] are also shown, as well as the ratio of the R_{AA} values, which is depicted in the bottom panel of the figure. The R_{AA} values at $\sqrt{s_{\text{NN}}} = 5.02$ TeV are compared with transport model calculations [24].

includes contributions from both prompt and non-prompt J/ψ. The upper (lower) limit of this calculation corresponds to a 10% (25%) contribution of nuclear shadowing.

Figure 3 shows that, in the explored rapidity interval, there is no significant variation of the R_{AA} values. The calculations of the transport model are in good agreement with the experimental results. The comparison of the results with those obtained at $\sqrt{s_{\text{NN}}} = 2.76$ TeV [14] hints (1.5σ) for a weaker suppression at $\sqrt{s_{\text{NN}}} = 5.02$ TeV at large y ($3.75 < y < 4$).

4.1.2 Centrality-differential R_{AA} as a function of y and p_T

Figures 4 and 5 show, respectively, the p_T and y dependence of the inclusive J/ψ R_{AA} , for events corresponding to the centrality classes 0–20%², 20–40% and 40–90%. In Fig. 4, moving from central to peripheral collisions, a weaker p_T dependence of the R_{AA} is observed, up to an almost constant nuclear modification factor for 40–90% centrality. When comparing results at $\sqrt{s_{\text{NN}}} = 5.02$ TeV and 2.76 TeV, a slight increase of the R_{AA} is visible for the most central collisions and for $2 < p_T < 6$ GeV/c at the higher collision energy, while the results are compatible in the 20–40% and 40–90% samples. A fair agreement with the transport model calculations is observed. The results for the 0–20% and 20–40% centrality classes are also compared with a model based on statistical hadronization (SHM) [63]. A good agreement can be found up to $p_T \sim 4$ GeV/c, while at higher transverse momentum R_{AA} is underestimated. This feature could partly be due to additional production mechanisms, not implemented in the model, such as J/ψ production from gluon fragmentation in jets.

In Fig. 5, the R_{AA} values exhibit a very weak rapidity dependence in all the centrality classes, as also observed in 0–90% (Fig. 3). The calculation of the transport model is able to describe the data, in

²The results for 0–20% were already published in Ref. [17]. In this paper, the values were updated with the improved $\langle T_{\text{AA}} \rangle$ uncertainties reported in Ref. [45].

Fig. 3: Inclusive J/ ψ nuclear modification factor as a function of rapidity for Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 5.02$ TeV in the 0–90% centrality class. The vertical error bars represent statistical uncertainties, the boxes around the points uncorrelated systematic uncertainties, while the correlated uncertainty is shown as a filled box around $R_{AA} = 1$. The corresponding measurements in Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 2.76$ TeV [14] are also shown, as well as the ratio of the R_{AA} values, which is depicted in the bottom panel of the figure. The R_{AA} values at $\sqrt{s_{\text{NN}}} = 5.02$ TeV are compared with transport model calculations [24].

particular when a weak nuclear shadowing scenario (10%, corresponding to the lower limit chosen by the authors) is adopted.

4.1.3 Centrality dependence of R_{AA}

In Figs. 6 and 7 the nuclear modification factor R_{AA} as a function of the average number of participant nucleons $\langle N_{\text{part}} \rangle$ is shown for various transverse momentum and rapidity intervals, respectively. The $\langle N_{\text{part}} \rangle$ intervals correspond to the centrality selections 0–10%, 10–20%, 20–30%, 30–40%, 40–50%, 50–60%, and 60–90%, from larger to smaller $\langle N_{\text{part}} \rangle$ values. The results of Fig. 6 clearly show that moving from low to high p_{T} the centrality dependence of R_{AA} becomes steeper, with R_{AA} reaching a minimum value of $0.29 \pm 0.02(\text{stat}) \pm 0.01(\text{syst})$ for the 0–10% centrality class and $8 < p_{\text{T}} < 12$ GeV/ c . In the low- p_{T} region ($0.3 < p_{\text{T}} < 2$ GeV/ c), the R_{AA} has a weak $\langle N_{\text{part}} \rangle$ dependence and is compatible with being constant (~ 0.7) for $\langle N_{\text{part}} \rangle > 150$. In the most peripheral centrality class, a deviation from unity can be observed, in particular for $p_{\text{T}} > 2$ GeV/ c , not seen in the theoretical calculations. As discussed in Refs [64, 65], the origin may be from the bias introduced by the event select and collision geometry, which causes an apparent suppression. When comparing the results with those corresponding to Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 2.76$ TeV [14], systematically higher R_{AA} values are found in the p_{T} interval $2 < p_{\text{T}} < 5$ GeV/ c , even if the maximum observed difference is only at 1.5σ level, for the centrality region 0–10%. In all other p_{T} intervals where the comparison is possible, the results at the two energies are compatible. When comparing the results with the transport model calculations, the agreement is good at low p_{T} ($0.3 < p_{\text{T}} < 2$ GeV/ c), while the data lie close to the upper edge of the calculation at higher p_{T} .

In Fig. 7 the centrality dependence of the nuclear modification factor is shown for 3 rapidity intervals. No variation of the suppression pattern against rapidity is observed. The same weak dependence can also be observed with the transport model calculations.

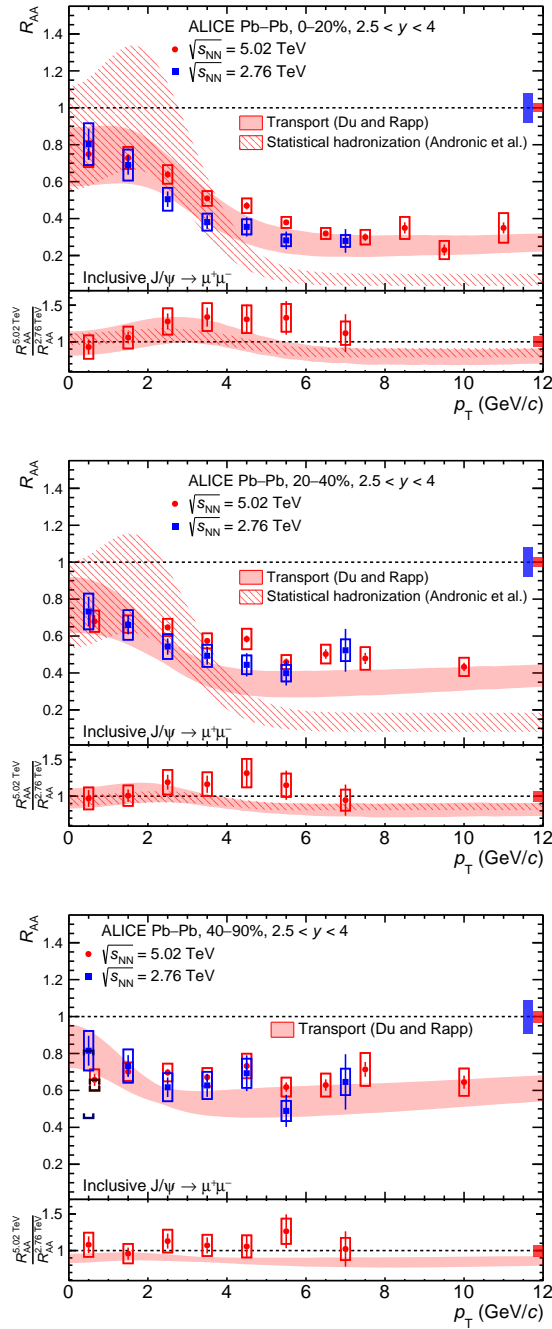

Fig. 4: Inclusive J/ψ nuclear modification factor as a function of p_T for Pb–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV in the 0–20% (top), 20–40% (middle) and 40–90% (bottom) centrality classes. The vertical error bars represent statistical uncertainties, the boxes around the points uncorrelated systematic uncertainties, while the correlated uncertainty is shown as a filled box around $R_{AA} = 1$. The corresponding measurements in Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV [14] are also shown, as well as the ratio of the R_{AA} values, which is depicted in the bottom panel of the figure. The R_{AA} values at $\sqrt{s_{NN}} = 5.02$ TeV and the ratios to lower energy results are compared with transport model calculations [24] and, for 0–20% and 20–40% centrality, with the results of the SHM [63]. The brackets around R_{AA} values for 40–90% centrality in the lowest p_T interval represent an estimate of the maximum influence of J/ψ photo-production, as detailed in Sec 4.1.

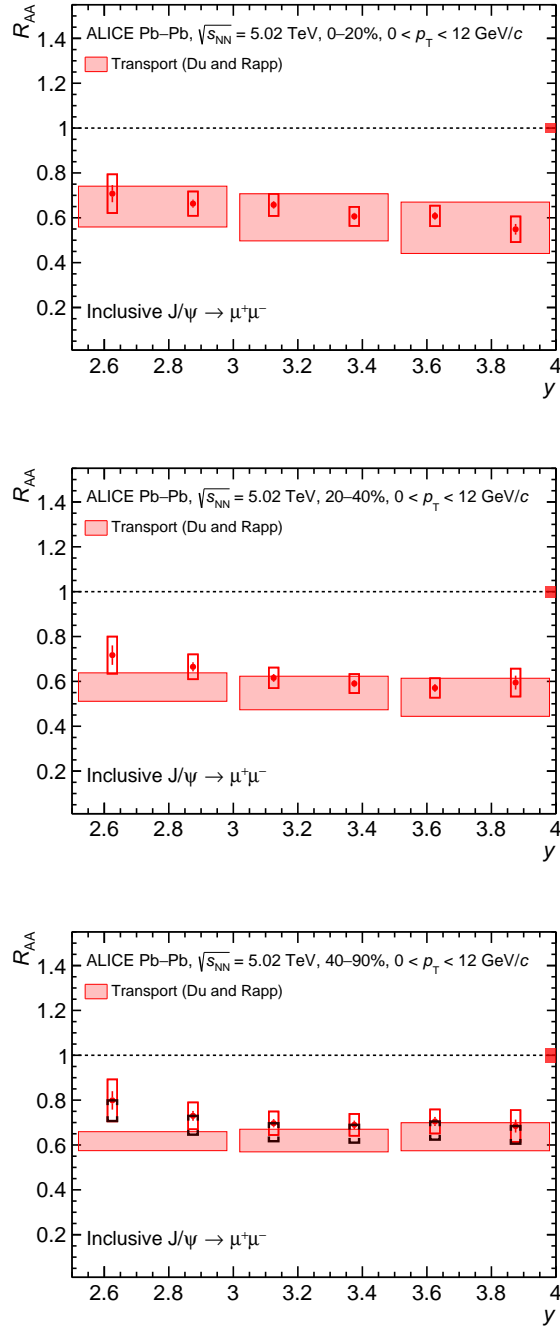

Fig. 5: Inclusive J/ψ nuclear modification factor as a function of rapidity for Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 5.02$ TeV in the 0–20% (top), 20–40% (middle) and 40–90% (bottom) centrality classes. The vertical error bars represent statistical uncertainties, the boxes around the points uncorrelated systematic uncertainties, while the correlated uncertainty is shown as a filled box around $R_{AA} = 1$. The R_{AA} values are compared with transport model calculations [24]. The brackets around R_{AA} values for 40–90% centrality represent an estimate of the maximum influence of J/ψ photo-production, as detailed in Sec 4.1.

4.2 J/ψ average transverse momentum and r_{AA}

A complementary insight into the modification of J/ψ transverse momentum distributions in Pb–Pb collisions can be obtained by the study of the J/ψ average transverse momentum $\langle p_T \rangle$ and the average squared

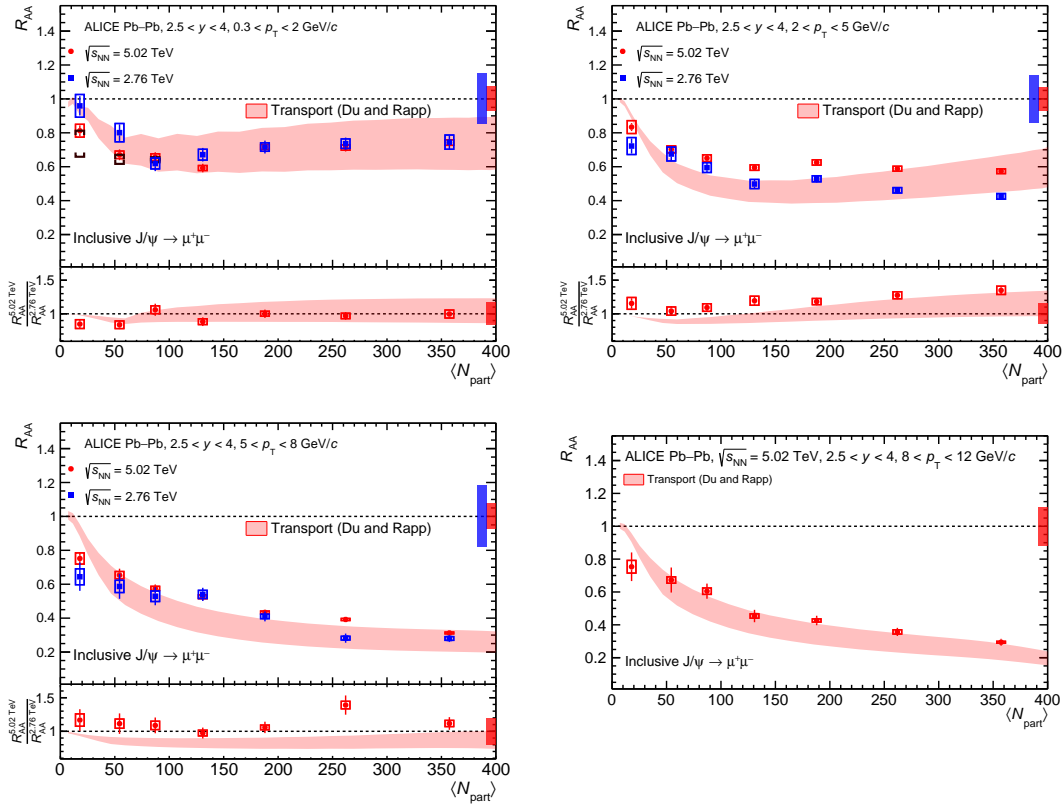

Fig. 6: Inclusive J/ψ nuclear modification factor as a function of $\langle N_{\text{part}} \rangle$ for Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 5.02$ TeV. Results are shown for four p_T intervals. The vertical error bars represent statistical uncertainties, the boxes around the points uncorrelated systematic uncertainties, while the correlated uncertainty is shown as a filled box around $R_{AA} = 1$. When the corresponding results at $\sqrt{s_{\text{NN}}} = 2.76$ TeV are available, the ratio of the results at the two energies is shown in the bottom section of each figure. The brackets around R_{AA} values for $0.3 < p_T < 2$ GeV/c represent an estimate of the influence of J/ψ photo-production, as detailed in Sec 4.1. The R_{AA} results at $\sqrt{s_{\text{NN}}} = 5.02$ TeV as well as the available ratios to the $\sqrt{s_{\text{NN}}} = 2.76$ TeV results are compared with transport model calculations [24].

momentum $\langle p_T^2 \rangle$ as a function of the collision centrality. By normalizing $\langle p_T^2 \rangle$ to the corresponding pp value, one obtains an adimensional quantity, $r_{AA} = \langle p_T^2 \rangle_{AA} / \langle p_T^2 \rangle_{pp}$, useful for comparisons between various collision energies and/or theory calculations.

As a first step, the J/ψ invariant yields as a function of p_T are fitted in various centrality classes with the following function

$$f(p_T) = C \cdot \frac{p_T}{\left(1 + (p_T/p_0)^2\right)^n}. \quad (4)$$

This function is widely used to reproduce the J/ψ p_T distribution in hadronic collisions (e.g Ref. [66, 67]). The quantities to be determined, $\langle p_T \rangle$ and $\langle p_T^2 \rangle$, are then computed as the first and second moment of $f(p_T)$ respectively. In Fig. 8, the J/ψ invariant yields as a function of p_T are shown for various centrality classes together with the fitted functions. In order to limit the influence of the J/ψ production excess at low p_T , due to photo-production, the interval $p_T < 0.5$ GeV/c was excluded from the fit. The statistical (systematic) uncertainties on $\langle p_T \rangle$ and $\langle p_T^2 \rangle$ were obtained from fits to the invariant yield distributions, considering only statistical (p_T -uncorrelated systematic) uncertainties on the J/ψ yields.

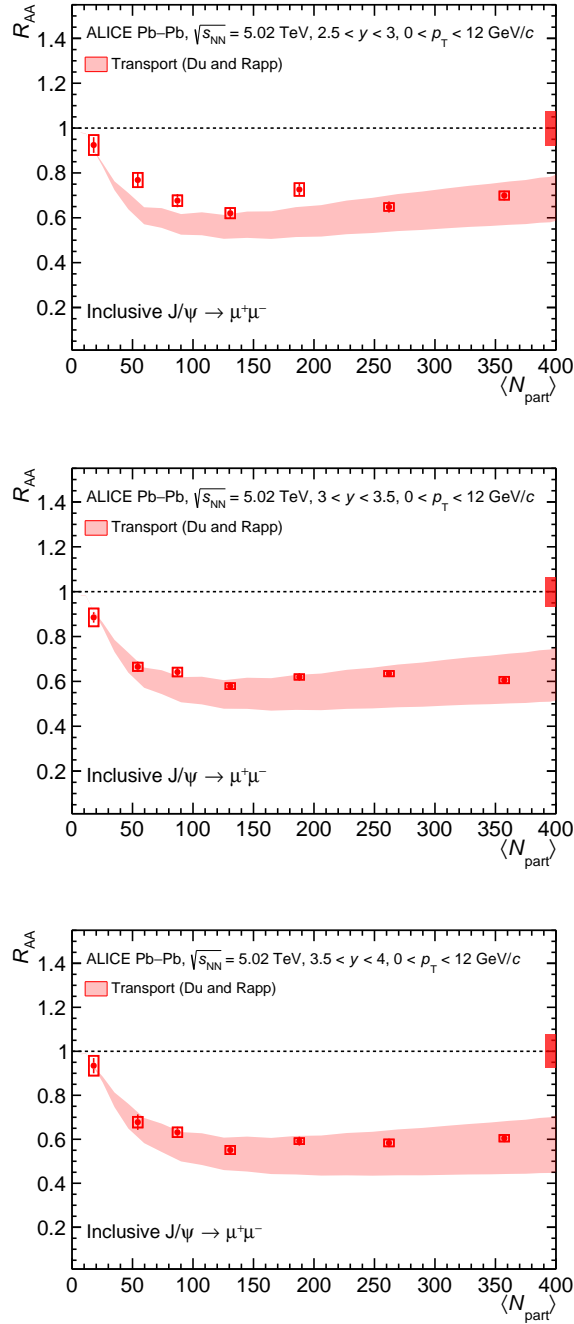

Fig. 7: Inclusive J/ ψ nuclear modification factor as a function of $\langle N_{\text{part}} \rangle$ for Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 5.02$ TeV, in the interval $0.3 < p_{\text{T}} < 12$ GeV/ c . Results are shown for three y intervals. The vertical error bars represent statistical uncertainties, the boxes around the points uncorrelated systematic uncertainties, while the correlated uncertainty is shown as a filled box around $R_{AA} = 1$. The results are compared with transport model calculations [24].

In the left panel of Fig. 9, the centrality dependence of $\langle p_{\text{T}} \rangle$ is shown and compared with previous results at $\sqrt{s_{\text{NN}}} = 2.76$ TeV [14]. The centrality dependence of the $\sqrt{s_{\text{NN}}} = 5.02$ TeV results is weak up to $\langle N_{\text{part}} \rangle \sim 150$, followed by a significant decrease towards central events. This softening of the J/ ψ p_{T} distributions is a direct consequence of the smaller suppression observed at low p_{T} when considering the transverse-momentum dependence of the nuclear modification factors, shown in Fig. 4. The $\langle p_{\text{T}} \rangle$

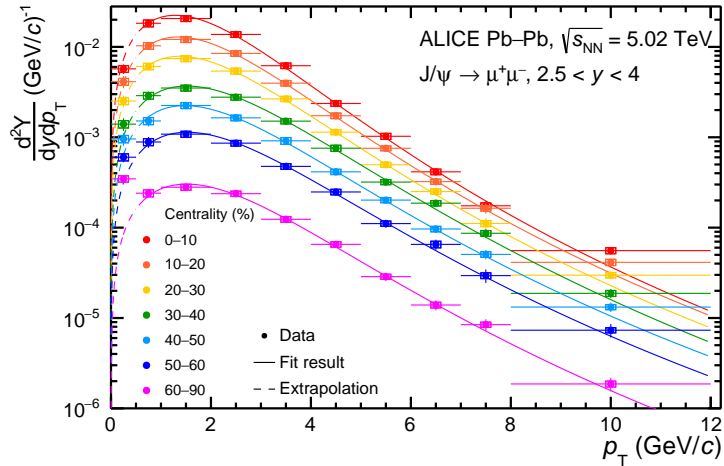

Fig. 8: p_T -differential yields for inclusive J/ψ in Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 5.02$ TeV, for various centrality classes. The vertical error bars represent the statistical uncertainties while the uncorrelated systematic uncertainties are represented by boxes around the points. The curves are the results of fits obtained using the function shown in Eq. 4. The dashed region corresponds to the region $p_T < 0.5$ GeV/c, excluded in the fits.

values are systematically larger than those at $\sqrt{s_{\text{NN}}} = 2.76$ TeV, an effect due to the increase of the collision energy, but the decrease of $\langle p_T \rangle$ with increasing centrality is similar at the two energies. A more direct comparison with lower energy results and theoretical calculations can be performed by studying the quantity r_{AA} . The results are shown in the right panel of Fig. 9, and compared with those obtained in Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 2.76$ TeV and the transport model calculations. In peripheral collisions, and up to $\langle N_{\text{part}} \rangle \sim 150$, the r_{AA} value is compatible with unity within uncertainties. A maximum decrease of $\sim 25\%$ is observed for central collisions. The brackets around the $\langle p_T \rangle$ and r_{AA} in peripheral collisions represent the possible variation of the hadronic J/ψ $\langle p_T \rangle$ and r_{AA} for two extreme hypotheses on the J/ψ photo-production contamination. The lower limit bracket corresponds to the assumption of no contribution from photo-produced J/ψ , while the upper one corresponds to the hypothesis that all the J/ψ with $p_T < 300$ MeV/c are photo-produced. The results are compatible with those at $\sqrt{s_{\text{NN}}} = 2.76$ TeV, with a hint for larger r_{AA} values at $\sqrt{s_{\text{NN}}} = 5.02$ TeV. A very different centrality dependence was observed at lower collision energies ($\sqrt{s_{\text{NN}}} = 200$ GeV at RHIC [68] and $\sqrt{s_{\text{NN}}} = 17$ GeV at SPS [69]) as the r_{AA} increases (especially at the SPS energy) towards more central collisions (the comparison was shown in Ref. [14]). The different behaviors of r_{AA} at different energies can be explained by the increasing amount of J/ψ regeneration with collision energy. Finally, the comparison with the transport model calculation [24] shows good agreement for peripheral and central collisions, but an underestimation of the data points is observed in the intermediate centrality class, reaching a significance up to 2.5σ for $\langle N_{\text{part}} \rangle \sim 150$.

5 Conclusions

This paper reports on ALICE measurements of the inclusive J/ψ production in Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 5.02$ TeV in the kinematic range $2.5 < y < 4$ up to $p_T < 12$ GeV/c. Results on the nuclear modification factor R_{AA} , the average transverse-momentum $\langle p_T \rangle$, and the ratio r_{AA} were presented. A systematic comparison with the calculation of a transport model was carried out and, for the p_T dependence of R_{AA} , with the results of a statistical hadronization model.

The inclusive J/ψ R_{AA} as a function of transverse momentum and rapidity for the centrality range 0–90%, is compatible with previously published results at $\sqrt{s_{\text{NN}}} = 2.76$ TeV [14]. A suppression of the

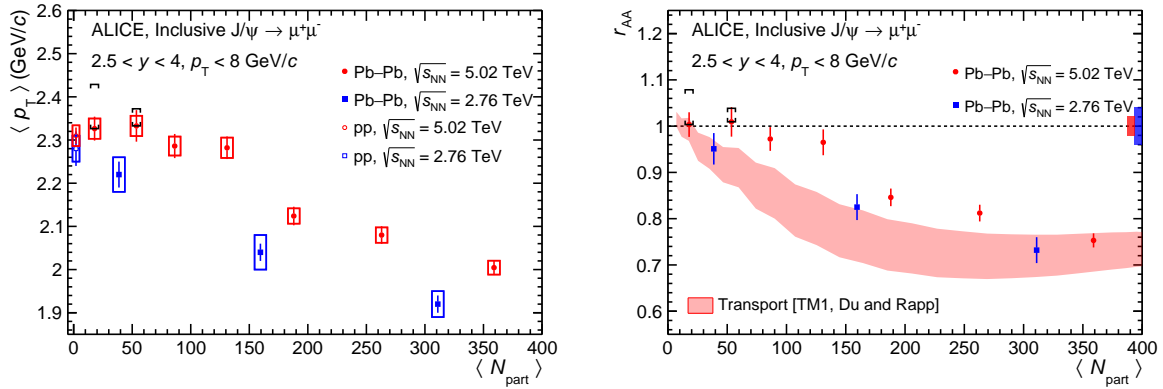

Fig. 9: (Left) Inclusive J/ψ $\langle p_T \rangle$ measured in Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 5.02$ TeV and $\sqrt{s_{\text{NN}}} = 2.76$ TeV, as a function of $\langle N_{\text{part}} \rangle$ for $p_T < 8$ GeV/c. The vertical error bars represent the statistical uncertainties, while the uncorrelated systematic uncertainties are shown as boxes around the points. J/ψ $\langle p_T \rangle$ results in pp collisions at the two collision energies are also shown at $\langle N_{\text{part}} \rangle = 2$. (Right) Inclusive J/ψ r_{AA} in Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 5.02$ TeV, compared with the $\sqrt{s_{\text{NN}}} = 2.76$ TeV results and a transport model calculation [24], as a function of $\langle N_{\text{part}} \rangle$ for $p_T < 8$ GeV/c. The vertical error bars represent the quadratic sum of statistical and systematic uncertainties on the numerator of the r_{AA} expression ($\langle p_T^2 \rangle_{\text{AA}}$), while the uncertainties on the denominator ($\langle p_T^2 \rangle_{\text{pp}}$) are shown as a filled box around unity.

J/ψ production is observed ($R_{\text{AA}} < 1$), mild at low p_T but increasing towards higher p_T , and not strongly depending on rapidity. The centrality-differential studies show that the y dependence of R_{AA} is weak and fairly independent of centrality, while the p_T dependence of R_{AA} grows steeper for more central events. All the R_{AA} results are fairly reproduced by the calculation of a transport model, with a tendency to underestimate the observed R_{AA} at intermediate p_T . The statistical hadronization model reproduces, although with larger uncertainties, the p_T dependence of R_{AA} for various centrality classes, but shows a discrepancy in the high- p_T region.

A complementary study was also carried out by measuring the centrality dependence of R_{AA} for different p_T and y intervals. A suppression strongly increasing with centrality is visible at high p_T , while at low p_T the suppression is relatively weak ($R_{\text{AA}} \sim 0.7$) and practically independent of centrality. On the contrary, the shape of the R_{AA} as a function of centrality does not vary significantly in the studied rapidity ranges, showing a mild decrease until $\langle N_{\text{part}} \rangle \sim 100$, followed by a plateau.

Finally, the r_{AA} ratio decreases with increasing centrality, similarly to previous observations at $\sqrt{s_{\text{NN}}} = 2.76$ TeV. The transport model calculation underestimates the measurement at intermediate $\langle N_{\text{part}} \rangle$ values.

The results shown in this paper confirm, with better accuracy, the observations carried out at $\sqrt{s_{\text{NN}}} = 2.76$ TeV and strengthen the evidence for the presence of a mechanism that leads to a significant increase of R_{AA} at low p_T . Recombination of charm-quark pairs during the deconfined QGP phase, as implemented in the transport model compared with our results, is a strong candidate for explaining the features of the data.

Acknowledgements

The ALICE Collaboration would like to thank all its engineers and technicians for their invaluable contributions to the construction of the experiment and the CERN accelerator teams for the outstanding performance of the LHC complex. The ALICE Collaboration gratefully acknowledges the resources and support provided by all Grid centres and the Worldwide LHC Computing Grid (WLCG) collaboration.

The ALICE Collaboration acknowledges the following funding agencies for their support in building and running the ALICE detector: A. I.
