Measurement of D_s^+ production and nuclear modification factor in Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV

ALICE Collaboration*

Abstract

The production of prompt D_s^+ mesons was measured for the first time in collisions of heavy nuclei with the ALICE detector at the LHC. The analysis was performed on a data sample of Pb–Pb collisions at a centre-of-mass energy per nucleon pair, $\sqrt{s_{NN}}$, of 2.76 TeV in two different centrality classes, namely 0–10% and 20–50%. D_s^+ mesons and their antiparticles were reconstructed at mid-rapidity from their hadronic decay channel $D_s^+ \rightarrow \phi \pi^+$, with $\phi \rightarrow K^- K^+$, in the transverse momentum intervals $4 < p_T < 12$ GeV/ c and $6 < p_T < 12$ GeV/ c for the 0–10% and 20–50% centrality classes, respectively. The nuclear modification factor R_{AA} was computed by comparing the p_T -differential production yields in Pb–Pb collisions to those in proton–proton (pp) collisions at the same energy. This pp reference was obtained using the cross section measured at $\sqrt{s} = 7$ TeV and scaled to $\sqrt{s} = 2.76$ TeV. The R_{AA} of D_s^+ mesons was compared to that of non-strange D mesons in the 10% most central Pb–Pb collisions. At high p_T ($8 < p_T < 12$ GeV/ c) a suppression of the D_s^+ -meson yield by a factor of about three, compatible within uncertainties with that of non-strange D mesons, is observed. At lower p_T ($4 < p_T < 8$ GeV/ c) the values of the D_s^+ -meson R_{AA} are larger than those of non-strange D mesons, although compatible within uncertainties. The production ratios D_s^+/D^0 and D_s^+/D^+ were also measured in Pb–Pb collisions and compared to their values in proton–proton collisions.

1 Introduction

Calculations of Quantum Chromodynamics (QCD) on the lattice predict that strongly-interacting matter at temperatures exceeding the pseudo-critical value of about $T_c \approx 145 - 165$ MeV and vanishing baryon density behaves as a deconfined Plasma of Quarks and Gluons (QGP) [1, 2]. In this state, partons are the relevant degrees of freedom and chiral symmetry is predicted to be restored. The conditions to create a QGP are expected to be attained in collisions of heavy nuclei at high energies. This deconfined state of matter exists for a short time (few fm/c), during which the medium created in the collision expands and cools down until its temperature drops below the pseudo-critical value T_c and the process of hadronisation takes place.

Heavy quarks (charm and beauty) are sensitive probes to investigate the properties of the medium formed in heavy-ion collisions. They are produced in quark-antiquark pairs predominantly at the initial stage of the collision in hard-scattering processes characterized by timescales shorter than the QGP formation time [3–5]. The heavy quarks propagate through the expanding hot and dense medium, thus experiencing the effects of the medium over its entire evolution. While traversing the medium, they interact with its constituents via both inelastic and elastic QCD processes, exchanging energy and momentum with the expanding medium [5, 6]. For heavy quarks at intermediate and high momentum, these interactions lead to energy loss due to medium-induced gluon radiation and collisional processes.

Evidence for heavy-quark in-medium energy loss is provided by the observation of a substantial modification of the transverse momentum (p_T) distributions of heavy-flavour decay leptons [7–10], D mesons [11, 12] and non-prompt J/ψ [13] in Au–Au and Pb–Pb collisions at RHIC and LHC energies as compared to proton–proton (pp) collisions. This modification is usually quantified by the nuclear modification factor R_{AA} , defined as the ratio between the yield measured in nucleus–nucleus collisions and the cross section in pp interactions scaled by the average nuclear overlap function. In absence of nuclear effects, R_{AA} is expected to be unity. Parton in-medium energy loss causes a suppression of hadron yields, $R_{AA} < 1$, at intermediate and high transverse momentum ($p_T > 3$ GeV/c). In central nucleus–nucleus collisions at RHIC and LHC energies, R_{AA} values significantly lower than unity were observed for heavy-flavour hadrons with p_T values larger than 3–4 GeV/c. In this p_T range, the D-meson yields measured in p–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV are consistent with binary-scaled pp cross sections [14], providing clear evidence that the suppression observed in Pb–Pb collisions is not due to cold nuclear matter effects and is induced by a strong coupling of the charm quarks with the hot and dense medium.

In case of substantial interactions with the medium, heavy quarks lose a significant amount of energy while traversing the fireball and may participate in the collective expansion of the system and possibly reach thermal equilibrium with the medium constituents. In this respect, the measurement of a positive elliptic flow v_2 of D mesons at LHC energies [15, 16] and of heavy-flavour decay electrons at RHIC energies [8, 9, 17] provides an indication that the interactions with the medium constituents transfer to charm quarks information on the azimuthal anisotropy of the system.

It is also predicted that a significant fraction of low- and intermediate-momentum heavy quarks could hadronise via recombination with other quarks from the medium [18–20]. An important role of hadronisation via (re)combination, either during the deconfined phase [21] or at the phase boundary [22], is indeed supported by the results of J/ψ nuclear modification factor and elliptic flow at low p_T [23–25]. Hadronisation via recombination allows in some models, e.g. [26–28], a better description of heavy-flavour production measurements at RHIC and LHC energies, in particular the R_{AA} of D^0 mesons at low p_T measured in Au–Au collisions at $\sqrt{s_{NN}} = 200$ GeV [12] and the positive and sizable D-meson v_2 in Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV [15].

The measurement of D_s^+ -meson production in Pb–Pb collisions can provide crucial additional information for understanding the interactions of charm quarks with the strongly-interacting medium formed in heavy-ion collisions at high energies. In particular, the D_s^+ -meson yield is sensitive to strangeness

production and to the hadronisation mechanism of charm quarks.

An enhancement of strange particle production in heavy-ion collisions as compared to pp interactions was long suggested as a possible signal of QGP formation [29, 30]. Strange quarks are expected to be abundant in a deconfined medium due to the short time needed to reach equilibrium values among the parton species and to the lower energy threshold for $s\bar{s}$ production. A pattern of strangeness enhancement increasing with the hadron strangeness content when going from pp (p–A) to heavy-ion collisions was observed at the SPS [31–34], at RHIC [35] and at the LHC [36]. In the frame of the statistical hadronisation models, strange particle production in heavy-ion collisions follows the expectation for a grand-canonical ensemble. In contrast, for pp collisions canonical suppression effects are found to be important, reducing the phase space available for strange particles [37, 38]. In this context, the increase in strange particle yields in heavy-ion collisions compared to pp interactions is viewed as due primarily to the lifting of the canonical suppression.

This strangeness enhancement effect could also affect the production of charmed hadrons if the dominant mechanism for D-meson formation at low and intermediate momenta is in-medium hadronisation of charm quarks via recombination with light quarks. Under these conditions, the relative yield of D_s^+ mesons with respect to non-strange charmed mesons at low p_T is predicted to be enhanced in nucleus–nucleus collisions as compared to pp interactions [39–41]. The comparison of the p_T -differential production yields of non-strange D mesons and of D_s^+ mesons in Pb–Pb and pp collisions is therefore sensitive to the role of recombination in charm-quark hadronisation.

A consequence of the possibly enhanced production of D_s^+ mesons in heavy-ion collisions would be a slight reduction of the fraction of charm quarks hadronising into non-strange meson species. Therefore, the measurement of the D_s^+ -meson production is also relevant for the interpretation of the comparison of the nuclear modification factors of non-strange D mesons and light-flavour hadrons (pions) [11, 42], which is predicted to be sensitive to the quark-mass and colour-charge dependence of parton in-medium energy loss [6, 43, 44]. Furthermore, due to this possible modification of the relative abundances of D-meson species, measuring the D_s^+ yield at low p_T is needed also to determine the total charm production cross section in Pb–Pb collisions.

The p_T -differential inclusive production cross section of prompt¹ D_s^+ mesons (average of particles and antiparticles) was measured in pp collisions at $\sqrt{s} = 7$ TeV with the ALICE detector and it was found to be described within uncertainties by perturbative QCD (pQCD) calculations [45]. The D_s^+ nuclear modification factor was measured in p–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV and found to be consistent with unity [14]. In this paper, we report on the measurement of prompt D_s^+ -meson production and nuclear modification factor in Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV. D_s^+ mesons (and their antiparticles) were reconstructed at mid-rapidity, $|y| < 0.5$, through their hadronic decay channel $D_s^+ \rightarrow \phi\pi^+$ with a subsequent decay $\phi \rightarrow K^-K^+$. The production yield was measured in two classes of collision centrality, central (0–10%) and semi-central (20–50%), and compared to a binary-scaled pp reference obtained by scaling the cross section measured at $\sqrt{s} = 7$ TeV to the Pb–Pb centre-of-mass energy via a pQCD-driven approach. The experimental apparatus and the data sample of Pb–Pb collisions used for this analysis are briefly presented in Section 2. In Section 3, the D_s^+ meson reconstruction strategy, the selection criteria and the raw yield extraction from the $KK\pi$ invariant mass distributions are discussed. The corrections applied to obtain the p_T -differential production yields of D_s^+ mesons, including the subtraction of the non-prompt contribution from beauty-hadron decays, are described in Section 4. The various sources of systematic uncertainty are discussed in detail in Section 5. The results on the D_s^+ -meson production yield and nuclear modification factor are presented in Section 6 together with the comparison to non-strange D-meson R_{AA} and to model calculations. The D_s^+/D^0 and D_s^+/D^+ yield ratios in three p_T intervals for

¹In this paper, ‘prompt’ indicates D mesons produced at the interaction point, either directly in the hadronisation of the charm quark or in strong decays of excited charm resonances. The contribution from weak decays of beauty hadrons, which gives rise to feed-down D mesons displaced from the interaction vertex, was subtracted.

the 10% most central Pb–Pb collisions are compared to those in pp collisions.

2 Apparatus and data sample

The ALICE detector and its performance are described in detail in Refs. [46] and [47], respectively. The apparatus consists of a central barrel covering the pseudorapidity region $|\eta| < 0.9$, a forward muon spectrometer ($-4.0 < \eta < -2.5$) and a set of detectors for triggering and event centrality determination. The detectors of the central barrel are located inside a 0.5 T magnetic field parallel to the LHC beam direction, that corresponds to the z -axis in the ALICE reference frame. The information provided by the following detectors was utilised to perform the analysis presented in this paper: the Inner Tracking System (ITS), the Time Projection Chamber (TPC) and the Time Of Flight (TOF) detector were used to reconstruct and identify charged particles at mid-rapidity, while the V0 detector provided the information for triggering, centrality determination and event selection. The neutron Zero Degree Calorimeters (ZDC) were also used, together with the V0 detector, for the event selection.

The trajectories of the D-meson decay particles are reconstructed from their hits in the ITS and TPC detectors. Particle identification is performed utilising the information from the TPC and TOF detectors. The ITS consists of six cylindrical layers of silicon detectors covering the pseudorapidity interval $|\eta| < 0.9$. The two innermost layers, located at 3.9 and 7.6 cm from the beam line, are composed of Silicon Pixel Detectors (SPD). The two intermediate layers are equipped with Silicon Drift Detectors (SDD) and the two outermost layers, with a maximum radius of 43.0 cm, are composed of double-sided Silicon Strip Detectors (SSD). The high spatial resolution of the ITS detectors, together with the low material budget ($\sim 7.7\%$ of a radiation length at $\eta = 0$) and the small distance from the interaction point, provides a resolution on the track impact parameter (i.e. the distance of closest approach of the track to the primary vertex) better than $65 \mu\text{m}$ for transverse momenta $p_T > 1 \text{ GeV}/c$ in Pb–Pb collisions [47]. The TPC, covering the pseudorapidity interval $|\eta| < 0.9$, provides track reconstruction with up to 159 points along the trajectory of a charged particle and allows its identification via the measurement of specific energy loss dE/dx . Particle identification is complemented with the particle time-of-flight measured with the TOF detector, which is composed of Multi-gap Resistive Plate Chambers and is positioned at 370–399 cm from the beam axis, covering the full azimuth and the pseudorapidity interval $|\eta| < 0.9$. The TPC and TOF information provides pion/kaon separation at better than 3σ level for tracks with momentum up to $2.5 \text{ GeV}/c$ [47].

The analysis was performed on a sample of Pb–Pb collisions at centre-of-mass energy per nucleon pair, $\sqrt{s_{\text{NN}}}$, of 2.76 TeV collected in 2011. The events were recorded with an interaction trigger that required coincident signals in both scintillator arrays of the V0 detector, covering the pseudorapidity ranges $-3.7 < \eta < -1.7$ and $2.8 < \eta < 5.1$, respectively. An online selection based on the V0 signal amplitude was used to record samples of central and semi-central collisions through two separate trigger classes. Events were further selected offline to remove background from beam-gas interactions on the basis of the timing information provided by the V0 and the neutron ZDC detectors (two hadronic calorimeters located at $z = 114 \text{ m}$ on both sides of the interaction point covering the interval $|\eta| > 8.7$). Only events with an interaction vertex reconstructed from ITS+TPC tracks with $|z_{\text{vertex}}| < 10 \text{ cm}$ were considered in the analysis.

Collisions were classified in centrality classes based on the sum of the signal amplitudes in the two V0 scintillator arrays. Each class is defined in terms of percentiles of the hadronic Pb–Pb cross section, as determined from a fit to the V0 signal amplitude distribution based on the Glauber-model description of the geometry of the nuclear collision and a two-component model for particle production [48]. The analysis was performed in two centrality classes: 0–10% and 20–50%. In total, 16.5×10^6 events, corresponding to an integrated luminosity $L_{\text{int}} = (21.5 \pm 0.7) \mu\text{b}^{-1}$, were analysed in the 0–10% centrality class, and 13.5×10^6 events, $L_{\text{int}} = (5.9 \pm 0.2) \mu\text{b}^{-1}$, in the 20–50% class. The average values of

the nuclear overlap function T_{AA} (proportional to the number N_{coll} of binary nucleon–nucleon collisions occurring in the Pb–Pb collision) for the two centrality classes are reported in Table 1.

Centrality class	$\langle T_{AA} \rangle$ (mb ⁻¹)	N_{evt}	L_{int} (μb ⁻¹)
0–10%	23.44 ± 0.76	16.4×10^6	21.3 ± 0.7
20–50%	5.46 ± 0.20	13.5×10^6	5.8 ± 0.2

Table 1: Average value of the nuclear overlap function, $\langle T_{AA} \rangle$, for the considered centrality classes, expressed as percentiles of the hadronic Pb–Pb cross section. The values were obtained with a Monte Carlo implementation of the Glauber model assuming an inelastic nucleon–nucleon cross section of 64 mb [48]. The number of analysed events and the corresponding integrated luminosity in each centrality class are also shown. The uncertainty on the integrated luminosity derives from the uncertainty of the hadronic Pb–Pb cross section from the Glauber model [48].

3 D_s⁺ meson reconstruction and selection

D_s⁺ mesons and their antiparticles were reconstructed in the decay channel $D_s^+ \rightarrow \phi \pi^+ \rightarrow K^- K^+ \pi^+$ (and its charge conjugate), whose branching ratio (BR) is $(2.24 \pm 0.10)\%$ [49]. Other D_s⁺ decay channels can give rise to the same $K^- K^+ \pi^+$ final state, such as $D_s^+ \rightarrow \bar{K}^{*0} K^+$ and $D_s^+ \rightarrow f_0(980) \pi^+$, with BR of $(2.58 \pm 0.11)\%$ and $(1.14 \pm 0.31)\%$, respectively [49]. However, as explained in Ref. [45], the applied cuts for the selection of the D_s⁺ signal candidates strongly reduce contributions from these channels, and therefore the measured yield is dominated by the $D_s^+ \rightarrow \phi \pi^+ \rightarrow K^- K^+ \pi^+$ decays. The decay channel through the ϕ resonance was chosen because the narrower width of the ϕ invariant-mass peak with respect to $f_0(980)$ and \bar{K}^{*0} provides the best discrimination between signal and background.

The analysis strategy for the extraction of the signal out of a large combinatorial background is based on the reconstruction of decay topologies with a secondary vertex significantly displaced from the interaction point. The secondary vertex position and its covariance matrix were determined from the decay tracks by using the same analytic χ^2 minimization method as for the computation of the primary vertex [50]. The resolution on the position of the D_s⁺ decay vertex was estimated with Monte Carlo simulations and it was found to be about 100 μm. D_s⁺ mesons have a mean proper decay length $c\tau = 150 \pm 2$ μm [49], which makes it possible to resolve their decay vertices from the primary vertex. With the current data sample, the signal of D_s⁺ mesons could be extracted in three p_T intervals (4–6, 6–8 and 8–12 GeV/c) in the 0–10% centrality class and in two p_T intervals (6–8 and 8–12 GeV/c) in the 20–50% centrality class.

D_s⁺ candidates were defined from triplets of tracks with the proper charge sign combination. Tracks were selected requiring $|\eta| < 0.8$ and $p_T > 0.6$ (0.4) GeV/c in the 0–10% (20–50%) centrality class. In addition, tracks were also required to have at least 70 (out of a maximum of 159) associated hits in the TPC, a $\chi^2/\text{ndf} < 2$ of the track momentum fit in the TPC and at least one associated hit in one of the two SPD layers. With these track selection criteria, the acceptance in rapidity for D mesons drops steeply to zero for $|y| \gtrsim 0.5$ at low p_T and for $|y| \gtrsim 0.8$ at $p_T \gtrsim 5$ GeV/c. A p_T -dependent fiducial acceptance cut was therefore applied on the D-meson rapidity, $|y| < y_{\text{fid}}(p_T)$, with $y_{\text{fid}}(p_T)$ increasing from 0.5 to 0.8 in $0 < p_T < 5$ GeV/c according to a second order polynomial function and taking a constant value of 0.8 for $p_T > 5$ GeV/c.

D_s⁺ candidates were filtered by applying kinematical cuts and geometrical selections on the decay topology, together with particle identification criteria. The selection criteria were tuned in each p_T interval and centrality class to have a good statistical significance of the signal, while keeping the selection efficiency as high as possible. It was also checked that background fluctuations were not causing a distortion in the signal line shape by verifying that the D_s⁺-meson mass and its resolution

were in agreement with the Particle Data Group (PDG) world-average value (1.969 GeV/ c^2 [49]) and the Monte Carlo simulation results, respectively. The resulting selection criteria depend on the transverse momentum of the candidate and provide a selection efficiency that increases with increasing p_T .

The main variables used to select the D_s⁺ decay topology were the decay length (L), defined as the distance between the primary and secondary vertices, and the cosine of the pointing angle ($\cos \theta_{\text{point}}$), which is the angle between the reconstructed D_s⁺ momentum and the line connecting the primary and secondary vertices. Additional selections were applied on the projections of decay length and cosine of pointing angle in the transverse plane xy (L_{xy} , $\cos \theta_{\text{point}}^{xy}$), in order to exploit the better resolution on the track parameters in that plane. A further cut was applied on L_{xy} divided by its uncertainty ($L_{xy}/\sigma_{L_{xy}}$). The three tracks were also required to have a small distance to the reconstructed decay vertex, by defining the variable σ_{vertex} as the square root of the sum in quadrature of the distances of each track to the secondary vertex. To further suppress the combinatorial background, the angles $\theta^*(\pi)$, i.e. the angle between the pion in the KK π rest frame and the KK π flight line in the laboratory frame, and $\theta'(K)$, i.e. the angle between one of the kaons and the pion in the KK rest frame, were exploited. The cut values used for D_s⁺ mesons with $4 < p_T < 6$ GeV/ c in the 0–10% centrality class were: $L, L_{xy} > 500 \mu\text{m}$, $L_{xy}/\sigma_{L_{xy}} > 7.5$, $\cos \theta_{\text{point}} > 0.94$, $\cos \theta_{\text{point}}^{xy} > 0.94$, $\sigma_{\text{vertex}} < 400 \mu\text{m}$, $\cos \theta^*(\pi) > 0.05$ and $|\cos^3 \theta'(K)| < 0.9$. Looser selection criteria were used for D_s⁺ selection at higher p_T and in more peripheral events, due to the lower combinatorial background.

In addition, to select D_s⁺ mesons decaying in the considered $\phi\pi^+$ mode, with $\phi \rightarrow K^-K^+$, candidates were rejected if none of the two pairs of opposite-charged tracks had an invariant mass compatible with the PDG world average for the ϕ mass (1.0195 GeV/ c^2 [49]). The difference between the reconstructed K⁺K⁻ invariant mass and world-average ϕ mass was required to be less than 4 MeV/ c^2 (a selection that preserves about 70% of the signal) for D_s⁺ candidates in the three p_T intervals considered in the 0–10% centrality class, while looser selections were used for semi-central events.

Particle identification was used to obtain a further reduction of the background. Compatibility cuts were applied to the difference between the measured signals and those expected for a pion or a kaon. A track was considered compatible with the kaon or pion hypothesis if both its dE/dx and time-of-flight were within 3σ from the expected values. Tracks without a TOF signal (mostly at low momentum) were identified using only the TPC information and requiring a 2σ compatibility with the expected dE/dx . Triplets of selected tracks were required to have two tracks compatible with the kaon hypothesis and one with the pion hypothesis. In addition, since the decay particle with opposite charge sign has to be a kaon, a triplet was rejected if the opposite-sign track was not compatible with the kaon hypothesis. This particle identification strategy preserves about 85% of the D_s⁺ signal.

For each candidate, two values of invariant mass can be computed, corresponding to the two possible assignments of the kaon and pion mass to the two same-sign tracks. Signal candidates with wrong mass assignment to the same-sign tracks would give rise to a contribution to the invariant-mass distributions that could potentially introduce a bias in the measured raw yield of D_s⁺ mesons. It was verified, both in data and in simulations, that this contribution is reduced to a negligible level by the particle identification selection and by the requirement that the invariant mass of the two tracks identified as kaons is compatible with the ϕ mass.

The invariant-mass distributions of the D_s⁺ candidates (sum of D_s⁺ and D_s⁻ candidates) are shown in Fig. 1 in the three p_T intervals for the 10% most central Pb–Pb collisions. The raw signal yields were extracted by fitting the invariant-mass distributions with a function that consists of the sum of a Gaussian term to describe the signal peak and an exponential function to describe the background. The fit was performed in the invariant-mass range $1.88 < M(\text{KK}\pi) < 2.1$ GeV/ c^2 in all p_T intervals. The lower limit of 1.88 GeV/ c^2 was chosen to exclude the contribution of D⁺ $\rightarrow K^-K^+\pi^+$ decays, BR = (0.265^{+0.008}_{-0.009})% [49], which could give rise to a bump in the background shape for invariant-mass values around the D⁺ mass

Centrality class	p_T interval (GeV/c)	$N^{D_s^\pm \text{ raw}} \pm \text{stat.}$	S/B (3σ)	$S/\sqrt{S+B}$ (3σ)	χ^2/ndf
0–10%	4–6	438 ± 144	0.02	3.0	27.4 / 18
	6–8	117 ± 38	0.10	3.2	17.5 / 18
	8–12	89 ± 21	0.38	5.0	26.5 / 18
20–50%	6–8	197 ± 61	0.07	3.5	9.9 / 21
	8–12	52 ± 20	0.29	3.4	17.9 / 21

Table 2: Measured raw yields ($N^{D_s^\pm \text{ raw}}$), signal over background (S/B), statistical significance ($S/\sqrt{S+B}$) and χ^2/ndf of the invariant-mass fit for D_s^+ and their antiparticles in the considered p_T intervals for the 0–10% and 20–50% centrality classes.

(1.870 GeV/c²) [49]. The mean values of the Gaussian functions in all the p_T intervals are compatible within two times their uncertainty with the PDG world average for the D_s^+ mass and the Gaussian widths are in agreement with the expected values from Monte Carlo simulations.

Figure 1: Invariant-mass distributions of D_s^+ candidates and charge conjugates in the three considered p_T intervals in the 10% most central Pb–Pb collisions.

In Table 2 the extracted raw yields of D_s^+ mesons (sum of particle and antiparticle), defined as the integral of the Gaussian functions, are listed for the different p_T intervals in both the considered centrality classes, together with the signal-over-background (S/B) ratios and the statistical significance ($S/\sqrt{S+B}$). The background was evaluated by integrating the background fit functions in $\pm 3\sigma$ around the centroid of the Gaussian.

4 Corrections

The raw yields extracted from the fits to the invariant-mass distributions of D_s^+ and D_s^- candidates were corrected to obtain the production yields of prompt (i.e. not coming from weak decays of B mesons) D_s^+ mesons. The p_T -differential yield of prompt D_s^+ was computed as

$$\left. \frac{dN^{D_s^+}}{dp_T} \right|_{|y|<0.5} = \frac{1}{\Delta p_T} \frac{1}{\text{BR} \cdot N_{\text{evt}}} \frac{f_{\text{prompt}}(p_T) \cdot \frac{1}{2} N^{D_s^\pm \text{ raw}}(p_T)}{2y_{\text{fid}}(p_T) (\text{Acc} \times \epsilon)_{\text{prompt}}(p_T)} \Big|_{|y|<y_{\text{fid}}}, \quad (1)$$

where $N^{D_s^\pm \text{ raw}}(p_T)$ are the values of the raw yields (sum of particles and antiparticles) reported in Table 2, which were corrected for the B-meson decay feed-down contribution (i.e. multiplied by the prompt fraction f_{prompt}), divided by the acceptance-times-efficiency for prompt D_s^+ mesons, $(\text{Acc} \times \epsilon)_{\text{prompt}}$, and

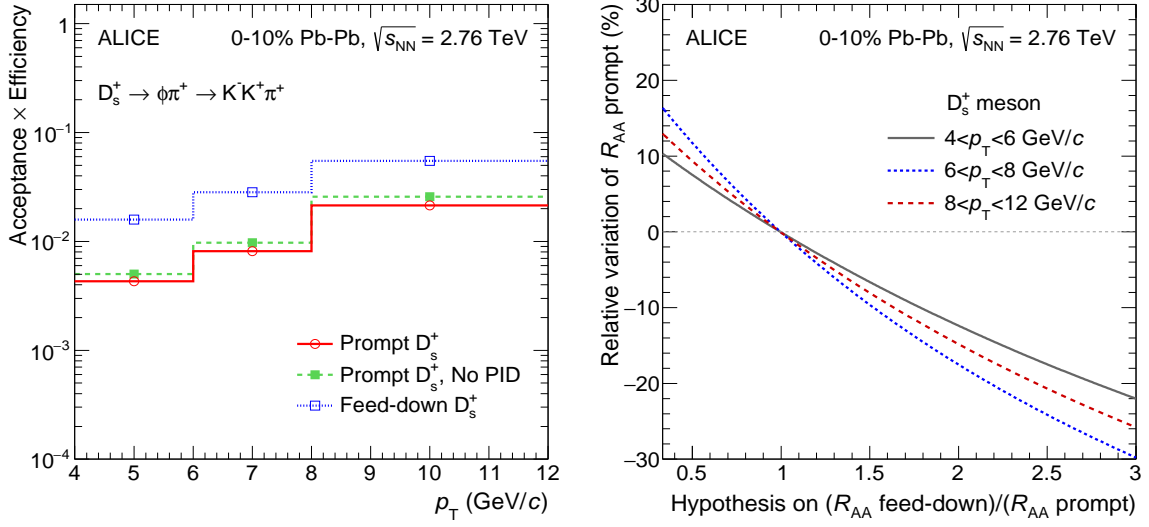

Figure 2: Left: Acceptance-times-efficiency for D_s^+ mesons in the 10% most central Pb–Pb collisions. The efficiencies for prompt (solid lines) and feed-down (dotted lines) D_s^+ mesons are shown. Also displayed, for comparison, the efficiency for prompt D_s^+ mesons without PID selections (dashed lines). Right: Relative variation of the prompt D_s^+ -meson yield in the 0–10% centrality class as a function of the hypothesis on $R_{AA}^{\text{feed-down}}/R_{AA}^{\text{prompt}}$ for the B feed-down subtraction approach based on Eq. (2).

divided by a factor of two to obtain the charge (particle and antiparticle) averaged yields. The corrected yields were divided by the decay channel branching ratio (BR), the p_T interval width (Δp_T), the rapidity coverage ($2y_{\text{fid}}$) and the number of analysed events (N_{evt}).

The correction for the acceptance and the efficiency was determined using Monte Carlo simulations. Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 2.76$ TeV were simulated using the HIJING v1.383 event generator [51]. Prompt and feed-down D_s^+ (and D_s^-) signals were added with the PYTHIA v6.4.21 generator [52]. In order to minimize the bias on the detector occupancy, the number of D mesons injected into each HIJING event was adjusted according to the Pb–Pb collision centrality. The p_T distribution of the generated D_s^+ mesons in the 0–10% centrality class was weighted in order to match the shape measured for D^0 mesons in central Pb–Pb collisions [42]. For the 20–50% centrality class, the generated p_T distribution was defined based on FONLL perturbative QCD calculations [53, 54] multiplied by the nuclear modification factor predicted by the BAMPS partonic transport model [55], which reproduces the measured non-strange D-meson R_{AA} in semi-central collisions within uncertainties [16].

The generated particles were transported through the ALICE detector using the GEANT3 [56] particle transport package together with a detailed description of the geometry of the apparatus and of the detector response. The simulation was tuned to reproduce the position and width of the interaction vertex distribution, the number of active electronic channels and the accuracy of the detector calibration, and their time evolution within the Pb–Pb data taking period.

The efficiencies were evaluated in centrality classes corresponding to those used in the analysis of the data in terms of charged-particle multiplicity, hence of detector occupancy. In the left-hand panel of Fig. 2, the $(\text{Acc} \times \varepsilon)$ values for prompt and feed-down D_s^+ mesons with rapidity $|y| < y_{\text{fid}}$ are shown for the 0–10% centrality class. The same figure shows also the $(\text{Acc} \times \varepsilon)$ values for the case without the PID selections, demonstrating that this selection is about 85% efficient for the signal.

The magnitude of $(\text{Acc} \times \varepsilon)$ increases with increasing p_T , from 0.4% in the lowest p_T interval up to 2% in $8 < p_T < 12$ GeV/c. The $(\text{Acc} \times \varepsilon)$ values for D_s^+ from beauty-hadron decays are larger than

those for prompt D_s⁺ by a factor of approximately 2.5–3.5 depending on p_T , because the decay vertices of the feed-down D_s⁺ mesons are more displaced from the primary vertex and they are, therefore, more efficiently selected by the analysis cuts. The efficiency of the selections used in the centrality interval 20–50% is higher by a factor of about two with respect to that in the most central events, because the smaller combinatorial background in semi-peripheral collisions allowed the usage of looser selections on the D_s⁺ candidates.

The ratio of prompt to inclusive contributions in the D_s⁺-meson raw yield, f_{prompt} , was evaluated using a procedure similar to the one adopted for the pp measurement [45]. The contribution of feed-down from B decays in the raw yield depends on p_T and on the applied geometrical selection criteria. The feed-down contribution was estimated using the beauty-hadron production cross section from FONLL perturbative QCD calculations for pp collisions at $\sqrt{s} = 2.76$ TeV scaled by the average nuclear overlap function $\langle T_{AA} \rangle$ in each centrality class, the B→D+X decay kinematics from the EvtGen package [57] and the Monte Carlo efficiencies for feed-down D_s⁺ mesons. The resulting sample of feed-down D_s⁺ mesons is composed of two contributions: about 50% of the feed-down originates from B_s⁰-meson decays, while the remaining 50% comes from decays of non-strange B mesons (B⁰ and B⁺). A hypothesis on the nuclear modification factor of feed-down D_s⁺ mesons, $R_{AA}^{\text{feed-down}}$, was introduced to account for the different modification of beauty and charm production in Pb–Pb collisions and for the possible enhancement of the B_s⁰ over non-strange B-meson yield due to the effect of hadronisation via recombination [58]. The fraction of prompt D_s⁺ yield was therefore computed in each p_T interval as

$$\begin{aligned} f_{\text{prompt}} &= 1 - \frac{N^{\text{D}_s^+ \text{ feed-down raw}}}{N^{\text{D}_s^+ \text{ raw}}} = \\ &= 1 - \langle T_{AA} \rangle \cdot \left(\frac{d^2\sigma}{dy dp_T} \right)_{\text{feed-down}}^{\text{FONLL}} \cdot R_{AA}^{\text{feed-down}} \cdot \frac{(\text{Acc} \times \epsilon)_{\text{feed-down}} \cdot 2y_{\text{fid}} \Delta p_T \cdot \text{BR} \cdot N_{\text{evt}}}{N^{\text{D}_s^+ \text{ raw}} / 2}, \end{aligned} \quad (2)$$

where $(\text{Acc} \times \epsilon)_{\text{feed-down}}$ is the acceptance-times-efficiency for feed-down D_s⁺ mesons. To determine the central value of f_{prompt} , it was assumed that the nuclear modification factors of feed-down and prompt D_s⁺ mesons were equal ($R_{AA}^{\text{feed-down}} = R_{AA}^{\text{prompt}}$). The resulting feed-down contribution is about 20–25% depending on the p_T interval. To determine the systematic uncertainty the hypothesis was varied in the range $1/3 < R_{AA}^{\text{feed-down}}/R_{AA}^{\text{prompt}} < 3$, as discussed in detail in Section 5. It should be noted that the central value and the range of the hypothesis on $R_{AA}^{\text{feed-down}}/R_{AA}^{\text{prompt}}$ differ from those used for non-strange D mesons in Refs. [15, 16, 42], owing to the unknown role of recombination in the beauty sector, which could enhance the ratio of B_s⁰ over non-strange B mesons, and to the large fraction of feed-down D_s⁺ mesons originating from non-strange B-meson decays.

The nuclear modification factor of D_s⁺ mesons was computed as

$$R_{AA}(p_T) = \frac{dN_{AA}^{\text{D}_s^+}/dp_T}{\langle T_{AA} \rangle d\sigma_{pp}^{\text{D}_s^+}/dp_T}. \quad (3)$$

The values of the average nuclear overlap function, $\langle T_{AA} \rangle$, for the considered centrality classes are reported in Table 1. The p_T -differential cross section of prompt D_s⁺ mesons with $|y| < 0.5$ in pp collisions at $\sqrt{s} = 2.76$ TeV, used as reference for R_{AA} , was obtained by scaling in energy the measurement at $\sqrt{s} = 7$ TeV [45]. The ratio of the cross sections from FONLL pQCD calculations [54] at $\sqrt{s} = 2.76$ and 7 TeV was used as the scaling factor. Since FONLL does not have a specific prediction for D_s⁺ mesons, the cross sections of the D-meson admixture (70% of D⁰ and 30% of D⁺) were used for the scaling. The theoretical uncertainty on the scaling factor was evaluated by considering the envelope of the results obtained by varying independently the factorisation and renormalisation scales and the charm quark mass, as explained in detail in Ref. [59]. For D⁰, D⁺ and D^{*+} mesons, the result of the scaling was validated by comparison with data [60].

Table 3: Relative systematic uncertainties on p_T -differential yields of prompt D_s⁺ mesons in Pb–Pb collisions for the two considered centrality classes.

5 Systematic uncertainties

The systematic uncertainties on the prompt D_s⁺-meson yields in Pb–Pb collisions are summarised in Table 3.

The systematic uncertainty on the raw yield extraction was estimated from the distribution of the results obtained by repeating the fit to the invariant-mass spectra varying i) the fit range and ii) the probability distribution functions used to model the signal and background contributions. In particular, a second order polynomial function was used as an alternative functional form to describe the background. The signal line shape was varied by using Gaussian functions with mean and width fixed to the world-average D_s⁺ mass and to the values expected from Monte Carlo simulations, respectively. Furthermore, the raw yield was also extracted by counting the entries in the invariant-mass distributions after subtraction of the background estimated from a fit to the side bands of the D_s⁺ peak. In case of fitting in an extended mass range, it was verified that the effect on the D_s⁺ yield due to the possible bump produced in the candidate invariant-mass distribution by $D^+ \rightarrow \phi\pi^+ \rightarrow K^-K^+\pi^+$ decays was negligible. An additional test was performed by fitting the D_s⁺ candidate invariant-mass distribution after subtracting the background estimated by coupling a pion track with K^+K^- pairs having an invariant mass in the side bands of the ϕ peak. The uncertainty was estimated to be 8% in all p_T intervals.

The contribution to the measured yield from D_s⁺ decaying into the $K^-K^+\pi^+$ final state via other resonant channels (i.e. not via a ϕ meson) was found to be negligible, due to the much lower selection efficiency, as discussed in Ref. [45].

Another source of systematic uncertainty originates from the imperfect implementation of the detector description in the Monte Carlo simulations, which could affect the particle reconstruction and identification, and the D_s⁺ selection efficiency.

The systematic uncertainty on the tracking efficiency (including the effect of the track selection) was estimated by comparing the efficiency (i) of track finding in the TPC and (ii) of track prolongation from the TPC to the ITS between data and simulations, and (iii) by varying the track quality selections. The estimated uncertainty is 5% per track, which results in 15% for the three-body decay of D_s⁺ mesons.

The effect of residual discrepancies between data and simulations on the variables used to select the D_s⁺ candidates was estimated by repeating the analysis with different geometrical selections on the decay topology and varying the cut on the compatibility between the K^+K^- invariant mass and the ϕ mass. A systematic uncertainty of 20% was estimated from the spread of the resulting corrected yields.

The systematic uncertainty induced by a different efficiency for particle identification in data and sim-

ulations was estimated by comparing the corrected D_s⁺ yields obtained using different PID approaches, testing both looser and tighter cuts with respect to the baseline selection described in Section 4. Due to the limited statistical significance, an analysis without PID selection could not be carried out. Such a test was performed in the analysis of D⁰ (→ K⁻π⁺), D⁺ (→ K⁻π⁺π⁺) and D^{*+} (→ D⁰π⁺) and a 5% uncertainty was estimated for the case of 3σ cuts on dE/dx and time-of-flight signals, which correspond to the loosest selections that could be tested for the D_s⁺. Based on all these checks a systematic uncertainty of 7% on the PID selection efficiency was estimated.

The efficiency is also sensitive to differences between the real and simulated D_s⁺ momentum distributions. The effect depends on the width of the p_T intervals and on the variation of the efficiency within them. A systematic uncertainty was defined from the relative difference among the efficiencies obtained using different p_T shapes for the generated D_s⁺ mesons, namely the measured dN/dp_T of D⁰ mesons in central Pb–Pb collisions, the p_T shape predicted by FONLL pQCD calculations with and without the nuclear modification predicted by the BAMPS partonic transport model. The resulting contribution to the systematic uncertainty was found to be 2% for the momentum interval 4 < p_T < 6 GeV/c, where the selection efficiency is strongly p_T dependent, and 1% at higher p_T.

The systematic uncertainty due to the subtraction of D_s⁺ mesons from B-meson decays was estimated following the procedure described in Ref. [11]. The contribution of the uncertainties inherent in the FONLL perturbative calculation was included by varying the heavy-quark masses and the factorisation and renormalisation scales, μ_F and μ_R, independently in the ranges 0.5 < μ_F/m_T < 2, 0.5 < μ_R/m_T < 2, with the constraint 0.5 < μ_F/μ_R < 2, where m_T = √(p_T² + m_Q²). Furthermore, the prompt fraction obtained in each p_T interval was compared with the results of a different procedure in which the FONLL cross sections for prompt and feed-down D mesons and their respective Monte Carlo efficiencies were the input for evaluating the correction factor

$$f'_{\text{prompt}} = \left(1 + \frac{(\text{Acc} \times \varepsilon)_{\text{feed-down}}}{(\text{Acc} \times \varepsilon)_{\text{prompt}}} \cdot \frac{\left(\frac{d^2\sigma}{dydp_T}\right)_{\text{feed-down}}^{\text{FONLL}}}{\left(\frac{d^2\sigma}{dydp_T}\right)_{\text{prompt}}^{\text{FONLL}}} \cdot \frac{R_{AA}^{\text{feed-down}}}{R_{AA}^{\text{prompt}}} \right)^{-1}. \quad (4)$$

Since FONLL does not have a specific prediction for D_s⁺ mesons, four different approaches were used to compute the predicted p_T shapes of promptly produced D_s⁺, (d²σ/dydp_T)_{prompt}^{FONLL}, as explained in detail in Ref. [45]: (i) FONLL prediction for the admixture of charm hadrons; (ii) FONLL prediction for D^{*+} mesons (the D^{*+} mass being close to that of the D_s⁺); (iii) FONLL prediction for c quarks and fragmentation functions from [61] with parameter r = (m_D - m_c)/m_D (m_D and m_c being the masses of the considered D-meson species and of the c quark, respectively); (iv) FONLL prediction for c quarks and fragmentation functions from [61] with parameter r = 0.1 (as used in FONLL calculations) for all meson species. In the latter two cases, the D_s^{*+} mesons produced in the c quark fragmentation were made to decay with PYTHIA and the resulting D_s⁺ were summed to the primary ones to obtain the prompt yield. The systematic uncertainty due to the B feed-down subtraction was finally evaluated as the envelope of the results obtained with the two methods, namely Eq. (2) and (4), when varying the FONLL parameters and the c → D_s⁺ fragmentation function used to determine (d²σ/dydp_T)_{prompt}^{FONLL} in Eq. (4).

The contribution due to the different nuclear modification factor of prompt and feed-down D_s⁺ mesons was estimated by varying the hypothesis on R_{AA}^{feed-down}/R_{AA}^{prompt} in the range 1/3 < R_{AA}^{feed-down}/R_{AA}^{prompt} < 3 for both feed-down subtraction methods. The variation of the hypothesis is motivated by the combined effect on the R_{AA} of (i) the different energy loss of charm and beauty quarks in the QGP, as predicted by energy loss models and supported by experimental data on D meson and non-prompt J/ψ R_{AA} at the LHC [11, 13, 42, 62, 63]; (ii) the possibly different contribution of coalescence in charm and beauty quark hadronisation, leading to a different abundance of D_s⁺ and B_s⁰ mesons relative to non-strange mesons; and

Table 4: Relative systematic uncertainties on the pp reference cross section.

(iii) the possibly different modulation of D and B spectra due to radial flow. The resulting uncertainty for the case of B feed-down subtraction approach based on Eq. (2) is shown in the right-hand panel of Fig. 2 for the three p_T intervals in the 0–10% centrality class.

The Pb–Pb data are also affected by a systematic uncertainty on the determination of the limits of the centrality classes, due to the 1.1% relative uncertainty on the fraction of the total hadronic cross section used in the Glauber fit [48]. This contribution was estimated from the variation of the D-meson dN/dp_T when the limits of the centrality classes are shifted by $\pm 1.1\%$. The resulting uncertainty, which is common to all p_T bins, is less than 1% for both the 0–10% and the 20–50% centrality classes.

Finally, the 4.5% uncertainty on the branching ratio [49] was considered.

In the calculation of the R_{AA} , the uncertainties on the reference cross section for pp collisions, the Pb–Pb yields, and the average nuclear overlap function were considered.

For the pp reference, the uncertainties on the measurement at $\sqrt{s} = 7$ TeV, described in Ref. [45] and those due to the FONLL-based scaling to $\sqrt{s} = 2.76$ TeV, described in Section 4, were summed in quadrature. The contributions to the systematic uncertainty on the pp reference cross section are reported in Table 4.

The uncertainties on the pp reference were added in quadrature to those on the Pb–Pb prompt D_s^+ yields, described above, except for the BR that cancels out in the ratio and the feed-down contribution deriving from FONLL uncertainties, that partly cancels in the ratio. This contribution was evaluated by comparing the R_{AA} values obtained with the two methods for feed-down correction of Eq. (2) and (4) and with the different heavy quark masses, fragmentation functions, factorisation and renormalisation scales used in FONLL. In this study, these variations were done simultaneously for the Pb–Pb yield and for the pp reference cross section, so as to take into account the correlations of these sources in the numerator and denominator of R_{AA} .

Finally, the R_{AA} normalisation uncertainty was computed as the quadratic sum of the 3.5% pp normalisation uncertainty [45], the contribution due to the 1.1% uncertainty on the fraction of hadronic cross section used in the Glauber fit discussed above, and the uncertainty on $\langle T_{AA} \rangle$, which is of 3.2% and 3.7% for the 0–10% and 20–50% centrality classes, respectively.

6 Results

The transverse momentum distributions dN/dp_T of prompt D_s^+ mesons in Pb–Pb collisions are shown in Fig. 3, for the 0–10% and 20–50% centrality classes. The yields reported in Fig. 3 refer to particles only, since they were computed as the average of particles and antiparticles under the assumption that the production cross section is the same for D_s^+ and D_s^- . The vertical error bars represent the statistical uncertainties. The symbols are positioned horizontally at the centre of each p_T interval, with the horizontal bars representing the width of the p_T interval. The systematic uncertainties from data analysis

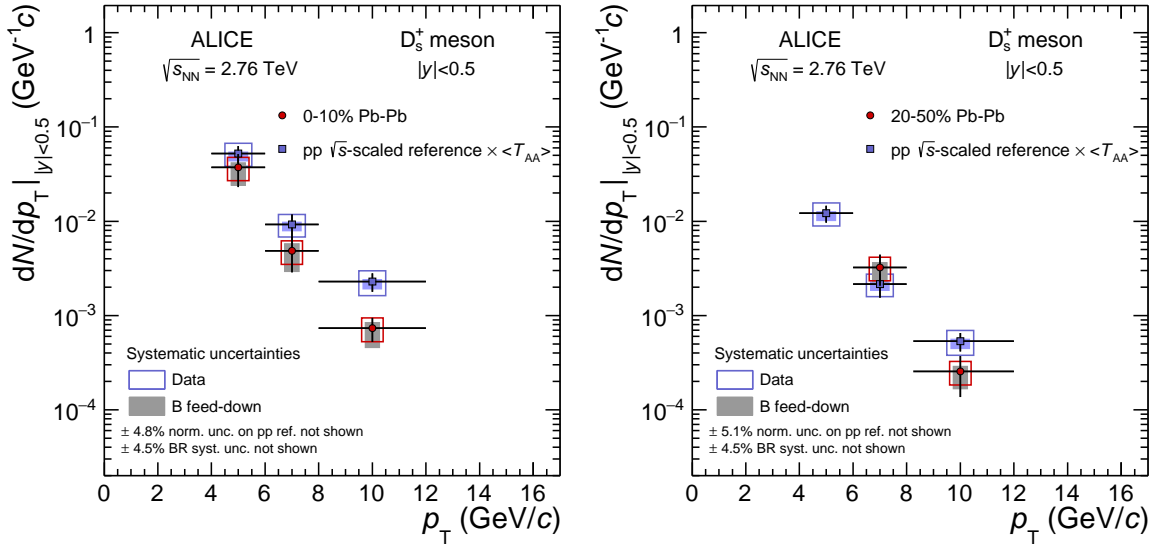

Figure 3: Transverse momentum distributions dN/dp_T of prompt D_s^+ mesons in the 0–10% (left panel) and 20–50% (right panel) centrality classes in Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV. Statistical uncertainties (bars), systematic uncertainties from data analysis (empty boxes) and systematic uncertainties due to beauty feed-down subtraction (shaded boxes) are shown. The reference pp distributions $\langle T_{AA} \rangle d\sigma/dp_T$ are shown as well.

are shown as empty boxes around the data points, while those due to the B feed-down subtraction, which include the contributions of the FONLL uncertainties and of the variation of the hypothesis on $R_{AA}^{\text{feed-down}}/R_{AA}^{\text{prompt}}$, are displayed as shaded boxes. The normalisation uncertainties are reported as text on the figures.

The p_T -differential yields measured in Pb–Pb collisions are compared to the reference yields in pp collisions at the same energy, scaled by the nuclear overlap function $\langle T_{AA} \rangle$, reported in Table 1. The pp reference at $\sqrt{s} = 2.76$ TeV is obtained by scaling the cross section measured at 7 TeV as described in Section 4. A clear suppression of the D_s^+ -meson yield in the 10% most central Pb–Pb collisions relative to the binary-scaled pp yields is observed in the highest p_T interval ($8 < p_T < 12$ GeV/c). In the 20–50% centrality class, an indication of suppression is found in $8 < p_T < 12$ GeV/c. At lower p_T , in both centrality classes, it is not possible to conclude on the presence of a suppression of the D_s^+ -meson yield in heavy-ion collisions with respect to the pp reference.

The nuclear modification factor R_{AA} of prompt D_s^+ mesons was computed from the dN/dp_T distributions. The results are shown as a function of p_T in the left-hand panel of Fig. 4 for the two centrality classes. The vertical bars represent the statistical uncertainties, the empty boxes are the total p_T -dependent systematic uncertainties described in Section 5, except for the normalisation uncertainty, which is displayed as a filled box at $R_{AA} = 1$. A suppression by a factor of about three of the D_s^+ -meson yield in Pb–Pb collisions relative to the binary-scaled pp cross section is observed in the highest p_T interval ($8 < p_T < 12$ GeV/c) for the 10% most central collisions. A smaller suppression (by a factor of about two) is measured in the 20–50% centrality class in $8 < p_T < 12$ GeV/c, even though with the current uncertainties no conclusions can be drawn on the centrality dependence of the D_s^+ -meson nuclear modification factor at high p_T . Since no significant modification of the D_s^+ -meson production relative to binary-scaled pp collisions is observed in p–Pb reactions in the p_T range considered here [14], the substantial suppression of the D_s^+ -meson yield at high p_T in Pb–Pb collisions cannot be explained in terms of initial state effects, but it is predominantly due to strong final-state effects induced by the hot and dense partonic medium created in the collisions of heavy nuclei. At lower p_T the central values of the measurement show a larger R_{AA} , however the large statistical and systematic uncertainties do not allow to draw a conclusion on the

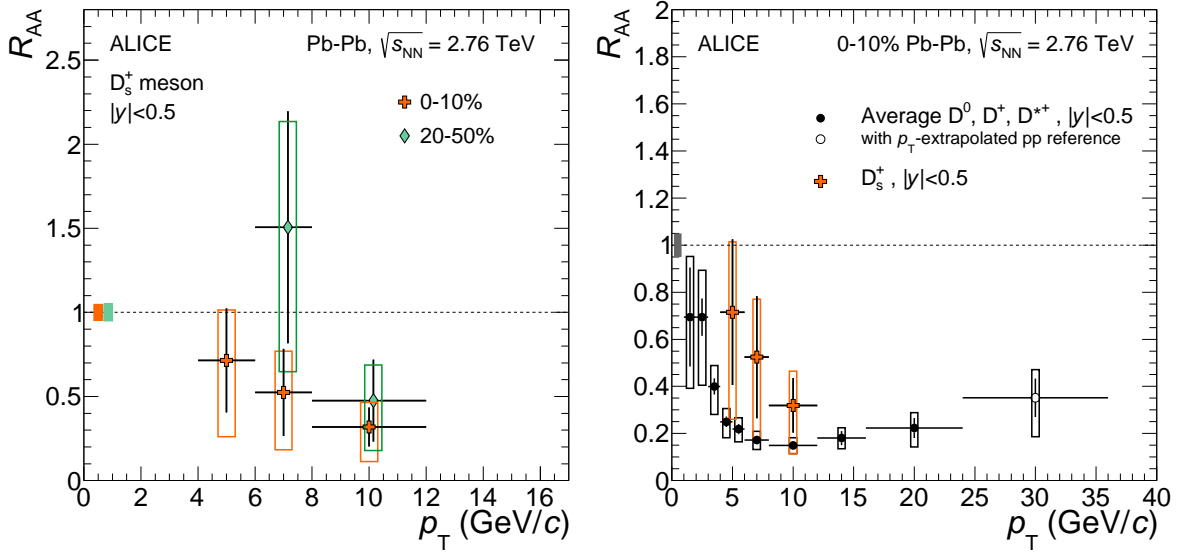

Figure 4: Left: R_{AA} of prompt D_s^+ mesons in the 0–10% and 20–50% centrality classes as a function of p_T . For the 20–50% case, the symbols are displaced horizontally for visibility. Right: R_{AA} of prompt D_s^+ mesons compared to non-strange D mesons (average of D^0 , D^+ and D^{*+} [42]) in the 0–10% centrality class. Statistical (bars), systematic (empty boxes), and normalisation (full box) uncertainties are shown.

p_T dependence of the D_s^+ nuclear modification factor.

The R_{AA} of prompt D_s^+ mesons in the 10% most central collisions is compared in the right-hand panel of Fig. 4 to the average nuclear modification factor of D^0 , D^+ and D^{*+} mesons measured in the same centrality class [42]. This comparison is meant to address the expected effect of hadronisation via quark recombination in the partonic medium on the relative abundances of strange and non-strange D-meson species. In the three p_T intervals, the values of the D_s^+ -meson R_{AA} are higher than those of non-strange D mesons, although compatible within uncertainties. Even considering that a part of the systematic uncertainty is correlated between strange and non-strange D mesons, the current uncertainties do not allow a conclusive statement on the expected enhancement of the D_s^+ -meson yield relative to that of non-strange D mesons in heavy-ion collisions.

An alternative approach to study the predicted modification of the charm-quark hadronisation in the presence of a QGP is to compare the ratios between the measured yields of D_s^+ and $D^0(D^+)$ mesons in Pb–Pb and pp collisions. This comparison is shown in Fig. 5 for the 10% most central Pb–Pb collisions. In the left-hand panel the D_s^+/D^0 ratio is displayed, while the right-hand panel shows the ratio D_s^+/D^+ . The ratios D_s^+/D^0 and D_s^+/D^+ in pp collisions are taken from the measurements at $\sqrt{s} = 7$ TeV [45]². No strong dependence on the collision energy is expected (see [45] and references therein). In the evaluation of the systematic uncertainties on the D-meson yield ratios, the sources of correlated and uncorrelated systematic effects were treated separately. In particular, the contributions of the yield extraction, topological selection efficiency and PID efficiency were considered as uncorrelated and summed in quadrature. The uncertainty on the tracking efficiency cancels completely in the ratios between production cross sections of meson species reconstructed from three-body decay channels (D^+ and D_s^+), while a 5% systematic uncertainty (4% in the pp case) was considered in the ratio to the D^0 yields, which are reconstructed from a two-particle final state. To propagate the uncertainty due to the B feed-down subtraction, the contribution of the FONLL cross section was treated as completely correlated among the D-meson species. It was estimated from the spread of the D-meson yield ratios obtained by

² The values from Ref. [45] were re-computed with the most recent value for the branching ratio of the $D_s^+ \rightarrow \phi\pi^+ \rightarrow K^-K^+\pi^+$ decay chain, which is 2.24% [49], while it was 2.28% at the time of the pp publication.

Figure 5: Ratios of prompt D-meson yields (D_s^+/D^0 and D_s^+/D^+) as a function of p_T in the 10% most central Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV compared to the results in pp collisions at $\sqrt{s} = 7$ TeV. Statistical (bars) and systematic (boxes) uncertainties are shown.

varying the factorisation and renormalisation scales and the heavy-quark mass in FONLL coherently for the three meson species. The contribution due to the hypothesis on $R_{AA}^{\text{feed-down}}/R_{AA}^{\text{prompt}}$ was considered as uncorrelated between D_s^+ and non-strange D mesons and summed in quadrature. The difference between the D_s^+/D^0 ratios in pp and in central Pb–Pb collisions is of about 1σ of the combined statistical and systematic uncertainties in both the two lowest p_T intervals, $4 < p_T < 6$ GeV/ c and $6 < p_T < 8$ GeV/ c . An enhancement of D_s/D ratios in heavy-ion collisions is predicted if recombination contributes to charm quark hadronisation in the QGP. However, considering the current level of experimental uncertainties, no conclusion on charm-quark hadronisation can be drawn from this first measurement of D_s^+ -meson production in Pb–Pb collisions.

In the framework of the Statistical Hadronisation Model [39,64,65], the p_T -integrated ratios of D-meson abundances for a chemical freeze-out temperature $T = 156$ MeV (as extracted from fits to the measured abundances of light-flavour hadrons [66]) and vanishing baryo-chemical potential, are expected to be $D_s^+/D^0 = 0.338$ and $D_s^+/D^+ = 0.830$, which are higher by a factor of about two with respect to the values calculated for pp collisions at LHC energies [45].

In Fig. 6, the measured R_{AA} of non-strange D mesons and of D_s^+ are compared to the prediction of the TAMU model [27, 58]. Among the several models available for open charm production in heavy-ion collisions, TAMU is the only one providing a quantitative prediction for the D_s^+ -meson nuclear modification factor. This is a heavy-quark transport model based on heavy-quark diffusion, implemented via simulations based on the relativistic Langevin equation, in a hydrodynamically expanding medium. The interactions of the charm quarks with the medium are modeled including only elastic processes, which are assumed to govern the heavy-quark scattering amplitudes at low and intermediate momenta. The heavy-quark transport coefficients are calculated within a non-perturbative T -matrix approach, where the interactions proceed via resonance formation that transfers momentum from the heavy quarks to the medium constituents. The hadronisation of charm quarks is performed via recombination with thermalized up, down and strange quarks. The remaining charm quarks are converted to hadrons using the vacuum fragmentation functions from [61] and fragmentation fractions $f(c \rightarrow D)$ from PYTHIA. This model predicts an enhancement of the D_s^+ over the non-strange D-meson R_{AA} at low p_T as a consequence of the recombination of charm quarks with thermally equilibrated strange quarks in the

Figure 6: R_{AA} of prompt D_s^+ and non-strange D mesons (average of D^0 , D^+ and D^{*+}) in the 0–10% centrality class compared to predictions of the TAMU model [58].

QGP. At higher p_T , where the dominant hadronisation mechanism is fragmentation, similar R_{AA} values are predicted for the different D-meson species. The model describes the measured D_s^+ -meson nuclear modification factor within uncertainties and at low p_T provides also a reasonable description of non-strange D-meson R_{AA} . The measured suppression of non-strange D mesons is underestimated at higher p_T , where the contribution of inelastic processes (gluon radiation), which are missing in this transport calculation, is expected to play a major role.

7 Summary

The production of D_s^+ mesons was measured for the first time in heavy-ion collisions. The measurement was carried out on a sample of Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV in two centrality classes, namely 0–10% and 20–50%.

The results for the 10% most central collisions indicate a substantial suppression ($R_{AA} \approx 0.3$) of the production of D_s^+ mesons at high p_T ($8 < p_T < 12$ GeV/c) with respect to the expectation based on the pp cross section scaled by the average nuclear overlap function. The observed suppression is compatible with that of non-strange D mesons and can be described by models including strong coupling of the charm quarks with the deconfined medium formed in the collision.

At lower momenta ($4 < p_T < 8$ GeV/c), the values of the D_s^+ -meson nuclear modification factor are larger than those of non-strange D mesons, although compatible within uncertainties. This result provides a possible hint for an enhancement of D_s/D ratio, which is expected if the recombination process significantly contributes to the charm quark hadronisation in the QGP.

The precision of the measurements will be improved using the larger data samples of Pb–Pb collisions that will be collected during the ongoing LHC Run-2. The larger sample size will allow us to observe the D_s^+ signal with less stringent selections, thus reducing the systematic uncertainty on the efficiency correction. In addition, the higher Pb–Pb collision centre-of-mass energy will reduce the impact of the \sqrt{s} -scaling of the pp reference. This will open the possibility to exploit the measurement of D_s^+ -meson production in heavy-ion collisions to assess the recombination effects in the charm-quark hadronisation and to provide further constraints to models describing the coupling of heavy quarks with the medium.

Acknowledgements

The ALICE Collaboration would like to thank all its engineers and technicians for their invaluable contributions to the construction of the experiment and the CERN accelerator teams for the outstanding performance of the LHC complex. The ALICE Collaboration gratefully acknowledges the resources and support provided by all Grid centres and the Worldwide LHC Computing Grid (WLCG) collaboration. The ALICE Collaboration would like to thank M. He, R. Fries and R. Rapp for making available their model calculations. The ALICE Collaboration acknowledges the following funding agencies for their support in building and running the ALICE detector: State Committee of Science, World Federation of Scientists (WFS) and Swiss Fonds Kidagan, Armenia; Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), Financiadora de Estudos e Projetos (FINEP), Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP); National Natural Science Foundation of China (NSFC), the Chinese Ministry of Education (CMOE) and the Ministry of Science and Technology of China (MSTC); Ministry of Education and Youth of the Czech Republic; Danish Natural Science Research Council, the Carlsberg Foundation and the Danish National Research Foundation; The European Research Council under the European Community’s Seventh Framework Programme; Helsinki Institute of Physics and the Academy of Finland; French CNRS-IN2P3, the ‘Region Pays de Loire’, ‘Region Alsace’, ‘Region Auvergne’ and CEA, France; German Bundesministerium für Bildung, Wissenschaft, Forschung und Technologie (BMBF) and the Helmholtz Association; General Secretariat for Research and Technology, Ministry of Development, Greece; Hungarian Országos Tudományos Kutatási Alapprogramok (OTKA) and National Office for Research and Technology (NKTH); Department of Atomic Energy and Department of Science and Technology of the Government of India; Istituto Nazionale di Fisica Nucleare (INFN) and Centro Fermi - Museo Storico della Fisica e Centro Studi e Ricerche “Enrico Fermi”, Italy; MEXT Grant-in-Aid for Specially Promoted Research, Japan; Joint Institute for Nuclear Research, Dubna; National Research Foundation of Korea (NRF); Consejo Nacional de Ciencia y Tecnología (CONACYT), Dirección General de Asuntos del Personal Académico (DGAPA), México, Amérique Latine Formation académique - European Commission (ALFA-EC) and the EPLANET Program (European Particle Physics Latin American Network); Stichting voor Fundamenteel Onderzoek der Materie (FOM) and the Nederlandse Organisatie voor Wetenschappelijk Onderzoek (NWO), Netherlands; Research Council of Norway (NFR); National Science Centre, Poland; Ministry of National Education/Institute for Atomic Physics and National Council of Scientific Research in Higher Education (CNCSI-UEFISCDI), Romania; Ministry of Education and Science of Russian Federation, Russian Academy of Sciences, Russian Federal Agency of Atomic Energy, Russian Federal Agency for Science and Innovations and The Russian Foundation for Basic Research; Ministry of Education of Slovakia; Department of Science and Technology, South Africa; Centro de Investigaciones Energéticas, Medioambientales y Tecnológicas (CIEMAT), E-Infrastructure shared between Europe and Latin America (EELA), Ministerio de Economía y Competitividad (MINECO) of Spain, Xunta de Galicia (Consellería de Educación), Centro de Aplicaciones Tecnológicas y Desarrollo Nuclear (CEADEN), Cubaenergía, Cuba, and IAEA (International Atomic Energy Agency); Swedish Research Council (VR) and Knut & Alice Wallenberg Foundation (KAW); Ukraine Ministry of Education and Science; United Kingdom Science and Technology Facilities Council (STFC); The United States Department of Energy, the United States National Science Foundation, the State of Texas, and the State of Ohio; Ministry of Science, Education and Sports of Croatia and Unity through Knowledge Fund, Croatia; Council of Scientific and Industrial Research (CSIR), New Delhi, India; Pontificia Universidad Católica del Perú.

- 84 Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States
- 85 Petersburg Nuclear Physics Institute, Gatchina, Russia
- 86 Physics Department, Creighton University, Omaha, Nebraska, United States
- 87 Physics Department, Panjab University, Chandigarh, India
- 88 Physics Department, University of Athens, Athens, Greece
- 89 Physics Department, University of Cape Town, Cape Town, South Africa
- 90 Physics Department, University of Jammu, Jammu, India
- 91 Physics Department, University of Rajasthan, Jaipur, India
- 92 Physik Department, Technische Universität München, Munich, Germany
- 93 Physikalisches Institut, Ruprecht-Karls-Universität Heidelberg, Heidelberg, Germany
- 94 Purdue University, West Lafayette, Indiana, United States
- 95 Pusan National University, Pusan, South Korea
- 96 Research Division and ExtreMe Matter Institute EMMI, GSI Helmholtzzentrum für Schwerionenforschung, Darmstadt, Germany
- 97 Rudjer Bošković Institute, Zagreb, Croatia
- 98 Russian Federal Nuclear Center (VNIIEF), Sarov, Russia
- 99 Russian Research Centre Kurchatov Institute, Moscow, Russia
- 100 Saha Institute of Nuclear Physics, Kolkata, India
- 101 School of Physics and Astronomy, University of Birmingham, Birmingham, United Kingdom
- 102 Sección Física, Departamento de Ciencias, Pontificia Universidad Católica del Perú, Lima, Peru
- 103 Sezione INFN, Bari, Italy
- 104 Sezione INFN, Bologna, Italy
- 105 Sezione INFN, Cagliari, Italy
- 106 Sezione INFN, Catania, Italy
- 107 Sezione INFN, Padova, Italy
- 108 Sezione INFN, Rome, Italy
- 109 Sezione INFN, Trieste, Italy
- 110 Sezione INFN, Turin, Italy
- 111 SSC IHEP of NRC Kurchatov institute, Protvino, Russia
- 112 Stefan Meyer Institut für Subatomare Physik (SMI), Vienna, Austria
- 113 SUBATECH, Ecole des Mines de Nantes, Université de Nantes, CNRS-IN2P3, Nantes, France
- 114 Suranaree University of Technology, Nakhon Ratchasima, Thailand
- 115 Technical University of Košice, Košice, Slovakia

- 116 Technical University of Split FESB, Split, Croatia
- 117 The Henryk Niewodniczanski Institute of Nuclear Physics, Polish Academy of Sciences, Cracow, Poland
- 118 The University of Texas at Austin, Physics Department, Austin, Texas, USA
- 119 Universidad Autónoma de Sinaloa, Culiacán, Mexico
- 120 Universidade de São Paulo (USP), São Paulo, Brazil
- 121 Universidade Estadual de Campinas (UNICAMP), Campinas, Brazil
- 122 University of Houston, Houston, Texas, United States
- 123 University of Jyväskylä, Jyväskylä, Finland
- 124 University of Liverpool, Liverpool, United Kingdom
- 125 University of Tennessee, Knoxville, Tennessee, United States
- 126 University of the Witwatersrand, Johannesburg, South Africa
- 127 University of Tokyo, Tokyo, Japan
- 128 University of Tsukuba, Tsukuba, Japan
- 129 University of Zagreb, Zagreb, Croatia
- 130 Université de Lyon, Université Lyon 1, CNRS/IN2P3, IPN-Lyon, Villeurbanne, France
- 131 V. Fock Institute for Physics, St. Petersburg State University, St. Petersburg, Russia
- 132 Variable Energy Cyclotron Centre, Kolkata, India
- 133 Warsaw University of Technology, Warsaw, Poland
- 134 Wayne State University, Detroit, Michigan, United States
- 135 Wigner Research Centre for Physics, Hungarian Academy of Sciences, Budapest, Hungary
- 136 Yale University, New Haven, Connecticut, United States
- 137 Yonsei University, Seoul, South Korea
- 138 Zentrum für Technologietransfer und Telekommunikation (ZTT), Fachhochschule Worms, Worms, Germany
