<b>Supplement .....</b>	<b>130</b>

## Zusammenfassung

In dieser Arbeit werden neue geochemische Daten zur Entwicklung von Krusten- und Mantelkomponenten im Hinblick auf ihre geochronologische Geschichte, sowie deren Randbedingungen, vorgestellt.

Zu diesem Zweck wurden zwei Lokalitäten ausgewählt. Das Rehoboth Terrane in Namibia, mit besonderem Bezug auf das Gibeon Kimberlit Feld, sowie die südöstliche vulkanische Provinz in Spanien (SEVP), mit besonderem Hinblick auf die Region um die Ortschaft von Casas de Tallante.

Das Rehoboth Terrane stellt eine tektonische Einheit im Süd Afrikanischen Gebiet dar. Aufgrund mächtiger Überlagerungen durch Sedimente ist das Wissen über den Aufbau und das Alter der darunterliegenden Kruste und Mantel nur sehr lückenhaft. Eine detaillierte Beschreibung der regionalen Geologie rund um das Rehoboth Terrane befindet sich in Kapitel 3.3.

Die SEVP ist geprägt durch verschiedene Stadien Neogener vulkanischer Aktivität. Informationen über die tiefere Kruste und den oberen Mantel, mit besonderem Bezug auf die zeitlichen Abfolgen, sind sehr spärlich. Ein detaillierterer geologischer Überblick über die SEVP befindet sich in Kapitel 5.3.

Charakteristisch für beide Arbeitsgebiete ist rezente vulkanische Aktivität, bei der Xenolithe von Kruste und Mantel an die Oberfläche befördert wurden.

Diese Xenolithe waren Gegenstand der hier vorliegenden Arbeit. Die Untersuchungen dieser Proben sollten einen Einblick in die Entwicklung der tieferen Kruste und des oberen Mantels der entsprechenden Region ermöglichen.

Ausgewählte Minerale der Xenolithe des Erdmantels beider Regionen wurden auf ihre Haupt- und Spurenelementkonzentrationen hin untersucht. Dies geschah mithilfe einer Elektronenstrahlmikrosonde und eines Laser ablations inductively coupled plasma Massenspektrometers (LA-ICPMS). Damit sollten geochemische Charakteristika, Anreicherungs- und Verarmungsprozesse, sowie Druck und Temperatur Randbedingungen ermittelt werden. Zusätzlich wurden Lu-Hf (Namibia und Spanien), Sm-Nd (Namibia und Spanien) und Sr (Spanien) Isotopien mithilfe eines Multicollector ICP Massenspektrometers

ermittelt, mit dem Ziel den Zeitpunkt von Mantelverarmungs- und der Anreicherungsprozesse zu datieren.

Bei den krustalen Proben wurden Zirkone von den krustalen Xenolithen und aus Ablagerungen von Tufflagen separiert. U-Th-Pb Isotopen wurden mithilfe von Laser Ablations ICPMS bestimmt mit dem Ziel das Alter der Kristallisation zu datieren. Darüber hinaus sollte die Bestimmung der Hf Isotopen derselben Zirkonkörner in denselben Wachstumszonen Informationen liefern über das geochemische Reservoir aus denen die Zirkone stammen. Die Kombination mit den zuvor bestimmten U-Th-Pb Isotopen erlaubt eine Aussage darüber zu treffen ob die Zirkone juvenil gebildet wurden, ob sie das Produkt eines krustalen Recyclings sind oder ob Krustenbereiche mit verschiedenen Isotopen miteinander vermischt wurden („crustal mixing“).

Schlussendlich bietet der Vergleich der neu gewonnenen Daten über Mantel und Kruste die Möglichkeit eine Hypothese zu erstellen inwiefern Mantel- und Krustenprozesse miteinander im Zusammenhang standen und ob Prozesse, die sich in einem Kompartiment abgespielt haben, in dem anderen widergespiegelt werden.

## **Entwicklung der unteren Kruste und des oberen Mantels des Rehoboth Terranes**

### *Mantel*

Insgesamt wurden 19 Mantelxenolithe (Granat Peridotite) aus den Kimberlit Diatremen Gibeon Townlands und Hanaus untersucht. Diese wurden vor etwa 72.5 Ma bei kimberlitischen Eruptionen an die Oberfläche befördert (Davies et al., 2001). Hauptelemente wurden bestimmt für Klinopyroxen, Granat, Olivin und Orthopyroxen, sowie Spurenelemente in Klinopyroxen und Granat.

Der Großteil der Proben fällt entlang eines geothermischen Gradienten von etwa 40 mW/m<sup>2</sup>, wohingegen sich eine kleinere Anzahl an Proben versetzt bei höheren Temperaturen und gleichbleibenden Drücken befindet. Alle Proben befinden sich im Graphit Stabilitätsfeld.

Die Muster der seltene Erdelemente (SEE) von Granaten und Klinopyroxenen zeigen, dass der Mantel unterhalb des Gibeon Kimberlit Feldes aus mindestens zwei verschiedenen Komponenten besteht (siehe Fig.0.1).

Der erste Typ (Typ „N“), dem 14 Proben entsprechen, zeigt normale SEE Muster und Grt/(Grt+CPX) Verhältnisse der modalen Gemengteile von etwa 0.5 bis etwa 0.8. Dem zweiten Typ (Typ „σ“) entsprechen 5 Proben. Charakteristisch sind die sigmoidalen SEE Muster mit Grt/(Grt+CPX) Verhältnissen von etwa 0.99.

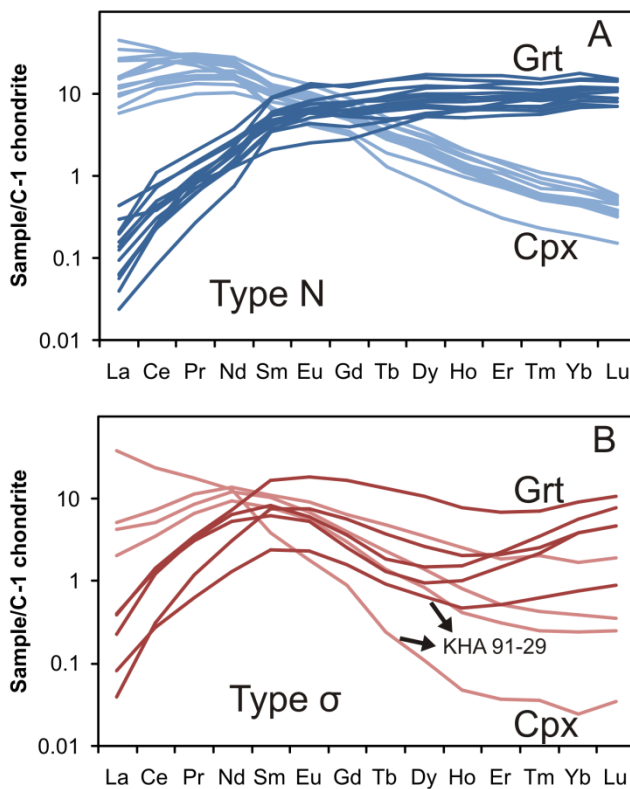

Fig.0.1 Typ „N“ (A; Blau) und Typ „σ“ (B; Rot) Proben, entsprechend ihrer SEE Muster von einander entsprechenden Klinopyroxenen und Granaten. Konzentrationen sind normiert auf C1 (McDonough and Sun, 1995)

Lu-Hf Isotopien beider Typen wurden mittels multicollector ICPMS bestimmt mit dem Ziel den Zeitpunkt der Verarmung der entsprechenden Mantelquelle zu bestimmen. Sm-Nd Isotopien derselben Proben wurden in einem zweiten Schritt bestimmt mit dem Ziel den Zeitpunkt der Anreicherung des entsprechenden Mantels durch Metasomatose zu bestimmen.

Die Normierung der Spurenelementkonzentrationen von Klinopyroxen und Granat auf eine primitive Probe aus Vitim (Sibirien) (Ionov et al., 2005) vor der Isotopenanalytik hat ergeben, dass beide Isotopensysteme metasomatisch überprägt worden sind. Aufgrund dessen entsprechen Alter, die auf Basis der beiden Isotopensysteme berechnet werden, Zeitpunkten der Anreicherung.

Fig.0.2 Lu-Hf (A) und Sm-Nd (B) Isotopien der Gesamtgesteine für typ „N“ (blau) und typ „σ“ (rot) Peridotite. Gezeigt ist die metasomatische Überprägung um einen Zeitpunkt von etwa 0.85 Ga für den erstgenannten und etwa 1.9 Ga für die zuletztgenannten Typ. Sm-Nd Isotopien der σ Peridotite deuten auf eine späte Anreicherung im Rahmen der Pan Afrikanischen Orogenese hin.

Die Korrelation der Lu-Hf Isotopie von vier Proben der „N“ Peridotite ergeben ein proterozoisches Anreicherungsalter von etwa 850 Ma, mit dem Ursprung aus einer leicht verarmten Mantelquelle ( $\epsilon\text{Hf}_{\text{initial}} = +3.3$ ).

Drei Proben mit sigmoidalen Granatmuster entsprechen einer Isochrone mit einem Alter von etwa 1.9 Ga. Der Initialwert von  $\epsilon\text{Hf}_{\text{initial}} = +29.4$  deutet auf eine stark verarmte Mantelquelle hin (Fig.0.2).

Die Ergebnisse der Sm-Nd Isotopien streuen. Dennoch fallen 3 Proben der σ Peridotite entlang einer Isochrone mit einem Alter von etwa 450 Ma, was einer metasomatischen Überprägung während der Pan Afrikanischen Orogenese entsprechen könnte.

Zusätzlich zu den eigenen Ergebnisse, präsentieren wir unsere Neuinterpretation eines zuvor publizierten Re-Os Datensatzes von Granat Peridotiten des Louwrensia Kimberlit Diatrem im

Gibeon Kimberlit Feld (Pearson et al., 2004), mit einer Isochrone die einem Alter von etwa 2.9 Ga entspricht. Die Vorstellung, dass Archaische Komponenten Bestandteil des Rehoboth Terranes sind, wurde bereits zuvor in verschiedenen anderen Studien vorgeschlagen (Hoal et al., 1995; Franz et al., 1996). Diese Vermutung wird zudem gestützt von Zirkonaltern im Bereich von 2.7 bis 2.9 Ga von Cornell et al. (2011) und Van Schijndel et al. (2011), sowie durch eigene Arbeiten (siehe Kapitel 4). Wir interpretieren dieses Alter als den Zeitpunkt der Verarmung der  $\sigma$  Peridotite.

Die Neuerkenntnisse, die durch diese Arbeit im Hinblick auf die Entwicklung des Mantels unterhalb des Gibeon Kimberlit Feldes gewonnen wurden, ermöglichen eine neue Interpretation der tektonischen Vorgänge, die das südliche Afrika geprägt haben.

Während des Zusammenschlusses des Ost- und Westblocks des Kaapvaalkratons wurden erste Mantelkomponenten des Rehoboth Terranes im Spinel Stabilitätsfeld gebildet, die im Anschluss unter bereits existierende Kruste subduziert und zu Granatperidotit umgewandelt wurde. Die Kollision des Rehoboth Terranes mit dem Kaapvaal Kraton um etwa 1.9 Ga führte zu einer Anreicherung dieses Mantels durch Metasomatose.

Während der Namaqua Orogenese zwischen 0.9 und 1.3 Ga, wurde neues Mantelmaterial unter das Rehoboth Terrane subduziert und in einem späten Stadium vor etwa 850 Ma, metasomatisch angereichert. Eine letzte Anreicherung hat eventuell bei der Pan Afrikanischen Orogenese vor etwa 450 Ma stattgefunden.

### *Kruste*

Die Bestimmung von Kristallisationsereignissen der tieferen Kruste unterhalb des Rehoboth Terranes, in Kombination mit den Ergebnissen der Anreicherungsverfahren im Mantel ermöglicht ein besseres Verständnis der tektonischen Vorgänge die das Terrane geformt haben.

Zirkone aus sechs krustalen Xenolithen, die von Karbonatitischen Diatremen, nahe des Gross Brukkaros Berges stammen, sowie Zirkone eines aus einem krustalen Xenolith des Louwrensia Kimberlit Schlots und aus einer weiteren Probe aus der Matrix des Louwrensia Kimberlits wurden in diesem Teil der Arbeit analysiert.

Mit Ausnahme der Probe aus der Matrix des Kimberlits, handelt es sich bei allen Proben um hochgradig metamorphe Gesteine.

Fig.0.3 U-Pb Altersspektren für Zirkone aus Xenolithen, die aus kimberlitischen Diatremen innerhalb des Gibeon Kimberlit Feldes oder aus karbonatitischen Diatremen nahe des Gross Brukkaros Berges stammen.

Im Anschluss an die Mineralseparation, der Einbettung und Politur, wurden die Zirkone mithilfe der Laser ablations ICPMS analysiert. Zuvor angefertigte Kathodenlumineszenz Bilder der Zirkone ermöglichten eine präzise Altersbestimmung der verschiedenen Wachstumszonen

innerhalb der Kristalle. Abhängig davon ob die Probe aus einem karbonatitischen oder kimberlitischen Diatrem stammt, ergibt sich ein unterschiedliches Bild für die Altersverteilung (Fig.0.3).

Abgesehen von einer Probe, die jüngere Zirkone vom Karbonatit selbst enthält (K3e), haben karbonatitische Xenolithe Altersmaxima hauptsächlich zwischen 1.0 und 1.5 Ga, wohingegen Zirkone aus Kimberlitischen Xenolithen zwischen 0.6 und bis zu 2.9 Ga variieren mit Hauptverteilungen um 1.1 bis 1.2 und 1.8 – 1.9 Ga. Die Probe aus der Matrix des Kimberlits zeigt ein wesentlich breiteres Altersspektrum, von 0.5 bis 2.9 Ga, wobei es sich bei den jüngeren Altern vermutlich um Zirkone aus den Nama Shales handelt.

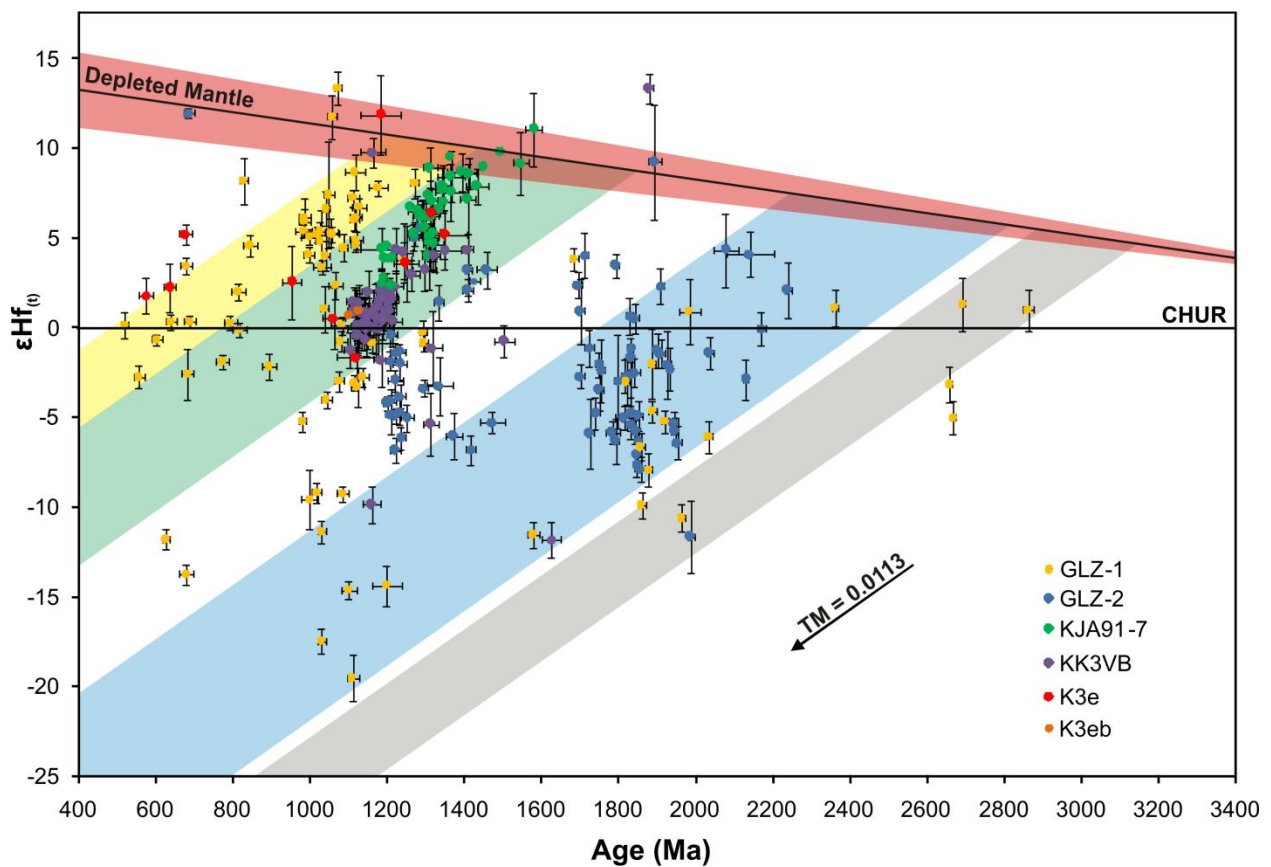

Fig.0.4 Hf Isotopien der Zirkone aus Gibeon und Umgebung in Kombination mit den entsprechenden U-Pb Altern. Vier Krustenwachstumstrends können mit Krustenrecycling und Krustenmischung identifiziert werden. Trends wurden berechnet mit einem  $^{176}\text{Lu}/^{177}\text{Hf}$  von 0.0113 (Rudnick and Gao, 2003).  $^{176}\text{Hf}/^{177}\text{Hf}$  Werte für den verarmten Mantel stammen aus Chauvel and Blichert-Toft (2001) und Vervoort et al. (1999).

Zusätzlich wurde die Hafnium Isotopie derselben Zirkone in denselben Wachstumszonen, direkt auf oder neben den Laserspots von den U-Th-Pb Analysen, bestimmt. Diese sollte in Kombination mit den U-Th-Pb Isotopien, eine Aussage über die Quelle aus der die Kruste entstanden ist, sowie Informationen über Krustenentstehung, Recycling oder die Mischung von isotopisch verschiebenden Krustenkompartimenten ermöglichen.

Vier Phasen krustalen Wachstums von einer verarmten Mantelquelle können basierend auf diesen Ergebnissen identifiziert werden (Fig.0.4).

Erstes Krustenwachstum von einer primitiven Mantelquelle fand im Archaikum in einem Zeitraum von 2.7 bis 2.9 Ga statt oder ausgehend von einer verarmten Mantelquelle mit Modellaltern zwischen 3.05 und 3.38 Ga.

Juvenile Kruste wurde gebildet zwischen 2.3 und 2.7 Ga von einer verarmten Mantelquelle mit anschließendem Recycling bis 1.0 und 1.2 Ga.

Der Zeitraum zwischen 1.5 und 1.6 Ga ist gekennzeichnet durch erneutes Krustenwachstum, ausgehend von einer verarmten Mantelquelle, sowie intensivem Krustenrecycling bis etwa 1.1 Ga und einem Krustenmischungstrend zwischen 1.3 und 1.1 Ga. Charakteristisch für diesen Zeitraum sind zudem die fast durchwegs positiven Werte für  $\epsilon\text{Hf}(t)$ . Etwa 60% aller Datenpunkte liegen im Zeitraum zwischen 1 und 1.4 Ga.

Jüngste Krustenbildung fand zwischen 0.8 und 1.1 Ga statt mit anschließendem Krustenrecycling im Rahmen der Pan Afrikanischen Orogenese bei etwa 0.5 bis 0.6 Ga.

Die Bandbreite und Variation der Probe aus der Kimberlitmatrix des Louwrensia Kimberlit Diatremes ist im Vergleich zu den übrigen Proben deutlich größer. Dies ist vermutlich darauf zurückzuführen, dass Zirkone aus den Nama Schiefen einen Teil der Probe ausmachen.

Im Hinblick auf die Unterschiede zwischen Proben aus Kimberliten und Proben aus Karbonatiten, kann geschlossen werden, dass verschiedene stratigraphische Einheiten beprobt worden sind.

Dieses Kapitel der Arbeit hat gezeigt, dass die Kruste unterhalb des Gibeon Kimberlit Feldes aus metamorphen Sedimenten aufgebaut wird. Unter Ausschluss der Zirkonalter der Nama Schiefer, liegen die jüngsten Alter der darunterliegenden Kruste bei etwa 0.9 Ga.

Die älteste Kruste ist vermutlich im Archaikum entstanden, gefolgt von einer Episode zwischen 1.8 und 1.9 Ga in der das Rehoboth Terrane mit dem Kaapvaal Kraton kollidiert ist.

Das zuletzt genannte Ereignis konnte zudem in den Erdmantelxenolithen der Gibeon Kimberlit Provinz in Form einer Anreicherung der  $\sigma$  Peridotite nachgewiesen werden (siehe Kapitel 3).

Subduktion unterhalb des Kalahari Kratons ist vermutlich der Grund für Krustenbildung, -recycling und -mischung in einem Zeitraum von 1.5 und 1.1 Ga, in dem sich etwa 60 % aller Datenpunkte dieser Studie befinden. Ein solches Szenario wurde bereits zuvor von Becker et al. (2006) vorgeschlagen.

Die Namaqua Orogenese hatte zudem auch einen Effekt auf die Kruste unterhalb des Gibeon Kimberlit Feldes in Form von juvenilem Krustenwachstum ausgehend von einer verarmten Mantelquelle und anschließendem Krustenrecycling während der Pan-Afrikanischen Orogenese. Während der Namaqua Orogenese wurden zudem neue Mantelkomponenten unterhalb des Gibeon Kimberlit Feldes hinzugefügt („N“ Peridotite), die anschließend gegen Ende derselben angereichert wurden. Der Effekt einer späten Überprägung während der Pan Afrikanischen Orogenese ist zudem erkennbar anhand der Sm-Nd Isotopie der  $\sigma$  Peridotite (siehe Kapitel 3).

## **Die untere Kruste und der obere Mantel der Südöstlich vulkanischen Provinz in Spanien**

### *Mantel*

Spinell / Plagioklas Peridotite des Neogenen Alkali basaltischen Vulkans Cabezo Negro de Tallante wurden gesammelt und ausgewählte Minerale von 11 Proben in einem nächsten Schritt separiert, mit Plagioklasen in nur 5 Proben. Haupt- und Spurenelemente von Klinopyroxenen und Orthopyroxenen, sowie Hauptelemente von Olivinen und Plagioklasen (falls vorhanden) wurden mit der Elektronenstrahlmikrosonde und eines Laser Ablations ICPMS gemessen. Sieben Proben wurden ausgewählt für isotopengeochemische Analysen, im Hinblick auf die Lu-Hf, Sm-Nd und Rb-Sr Isotopensysteme.

Alle ausgewählten Proben stammen aus einem Druckbereich zwischen 7 und 20 kbar und einem Temperaturbereich zwischen 900 und 1000°C. Temperaturen wurden ermittelt mithilfe des zwei Pyroxen Thermometers von Brey and Koehler (1990), der Druck mithilfe des Ca in Olivin Barometers von Koehler and Brey (1990).

Ausgehend von den Spurenelementkonzentrationen, konnten drei verschiedene Typen von Spurenelementmustern unterschieden werden. Typ eins ist charakterisiert durch eine leichte

Anreicherung der mittleren seltenen Erden (MSEE) und relativ dazu leicht verarmten leichten seltenen Erden (LSEE) (siehe Fig.0.5 – grün). Typ zwei ist gekennzeichnet durch fast flache seltene Erdelementmuster und insgesamt niedrigeren Gehalten an seltenen Erdelementen im Vergleich zu Typ 1 (siehe Fig.0.5 – rot). Typ drei ist vertreten durch lediglich eine Probe, die stark angereichert ist an LSEE, wohingegen die entsprechenden MSEE und schweren seltenen Erdelemente (HSEE) im Allgemeinen fast den Muster von Typ 1 entsprechen (siehe Fig.0.5 – blau).

Fig.0.5 Drei Typen von Proben für Spinell / Plagioklas Peridotite von Cabezo Negro de Tallante werden unterschieden anhand der SEE Muster der entsprechenden Klinopyroxene, normiert auf C1 (McDonough and Sun, 1995). Typ 1 wird dargestellt durch die Farbe grün, Typ 2 durch die Farbe rot und Typ 3 durch die Farbe blau.

Die Normierung auf eine primitive Probe aus Vitim (Sibirien) (Ionov et al., 2005) zeigt, dass alle drei Typen eine Anreicherung der leichten seltenen Erden erfahren haben.

Die Lu-Hf Isotopien der gemessenen Proben zeigen keine eindeutige Korrelation aufgrund des kleinen Bereichs für  $^{176}\text{Lu}/^{177}\text{Hf}$  und aufgrund von Streuung der Datenpunkte. Durch Hinzunahme eines weiteren Datenpunkts (TL16) derselben Lokalität aus einer früheren Publikation (Beccaluva et al., 2004; Bianchini et al., 2011), können vier Datenpunkte miteinander zu einem Alter von etwa 550 Ma korreliert werden (Fig.0.6). Da Hf offensichtlich keine Anreicherung widerfahren ist, könnte dieses Alter einem Verarmungsalter unterhalb der SEVP entsprechen.

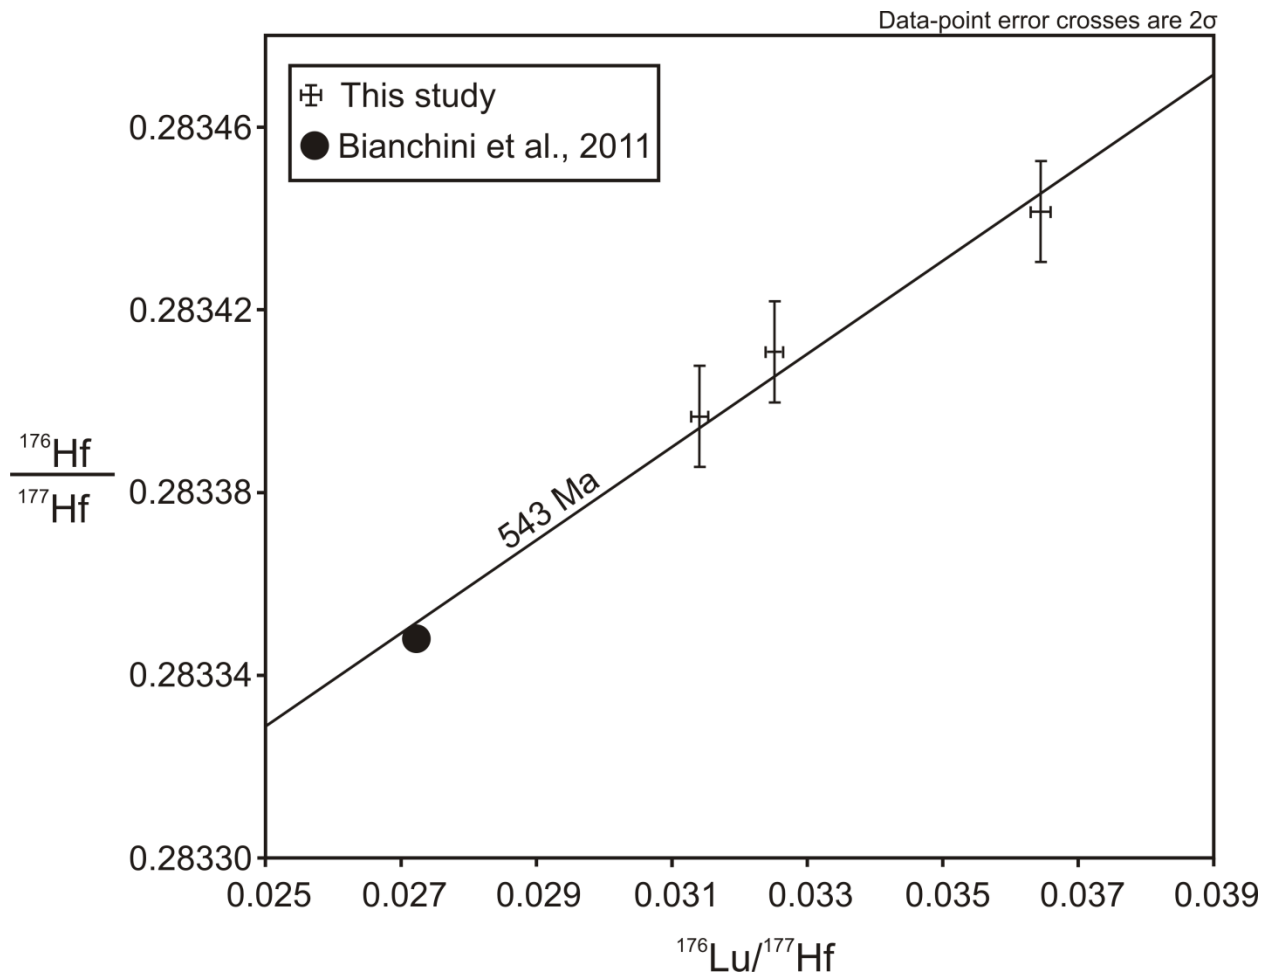

Fig.0.6: Eine mögliche Mantelverarmung zu einem Zeitpunkt von etwa 550 Ma könnte stattgefunden haben. Drei Datenpunkte dieser Studie und ein weiterer Datenpunkt, publiziert von Bianchini et al. (2011) und Beccaluva et al. (2004) fallen entlang einer entsprechenden Referenzisochrone.

Das Hf Modellalter zweier weitere Proben deuten auf die Präsenz von älteren Komponenten unterhalb der SEVP hin, im Einklang mit isotopischen Studien der Tallante Xenolithe von

Bianchini et al. (2011) und anderen Lokalitäten innerhalb Europas (Downes and Dupuy, 1987; Reisberg et al., 1989; Bodinier et al., 1991; Downes et al., 1991; Zangana et al., 1997; Beccaluva et al., 2001; Downes et al., 2002).

Isotopien für Sm-Nd entsprechen keiner einheitlichen Isochrone, sie streuen jedoch um eine Projektion von etwa 550 Ma.

Sr Isotopien der Klinopyroxene und Plagioklase weichen voneinander ab.  $^{87}\text{Sr}/^{86}\text{Sr}$  Isotopenverhältnisse der Plagioklase sind höher im Vergleich zu denen der Klinopyroxene. Die erhöhten Isotopenverhältnisse der Plagioklase sind vermutlich zurückzuführen auf eine Interaktion mit den alkali basaltischen Schmelzen, die die Mantelxenolithe and die Oberfläche befördert haben. Die Klinopyroxene scheinen von diesem Ereignis keine Anreicherung widerfahren zu haben.

### *Kruste*

Drei Proben von alkali basaltischen Aufschlüssen innerhalb der SEVP wurden untersucht mit dem Ziel die Entwicklung der unteren Kruste dieses Gebiets zu entschlüsseln. Die Probennahme erfolgte entweder aus Tufflagen (CNTS-1 und ALCS-1) oder aus der Matrix der alkali Basalte (CG-Z1 – CG-Z3). In einem ersten Schritt wurden die Proben im Gelände gesiebt, gefolgt von Schwereretrennung, Magnettrennung, einer Behandlung mit 6 M HCl, einer Siebung mit Einmal-Sieben und einer Separation mithilfe eines Stereomikroskops.

Wachstumszonen innerhalb der Zirkonkristalle wurden sichtbar gemacht mithilfe von Kathodenlumineszenz Bildern. U-Th-Pb Isotopien von homogenen Wachstumszonen wurden anschließend mittels laser Ablations ICPMS bestimmt. Anschließend wurde die Hf Isotopie der entsprechenden Wachstumszonen mittels Laser Ablation multicollector ICPMS ermittelt. Die Kombination beider Informationen ermöglichte einen besseren Einblick in die Entwicklungsgeschichte der Kruste unterhalb der SEVP im Hinblick auf juveniles Krustenwachstum, Krustenrecycling und Krustenmischungsprozessen.

Alle drei Proben zeigen sehr ähnliche Altersverteilungsmuster mit einer großen Altersspanne zwischen 2.6 Ma und 3 Ga. Hauptaltersverteilungsbereiche liegen zwischen 0.3 und 0.4, 0.5 und 0.6 bis 0.7 Ga. Geringere Alterspopulationen liegen zwischen 1 Ga bis 1.1 Ga, 1.8 bis 2.2 Ga, 2.4 bis 2.6 Ga und 2.9 bis 3 Ga (Fig.0.7).

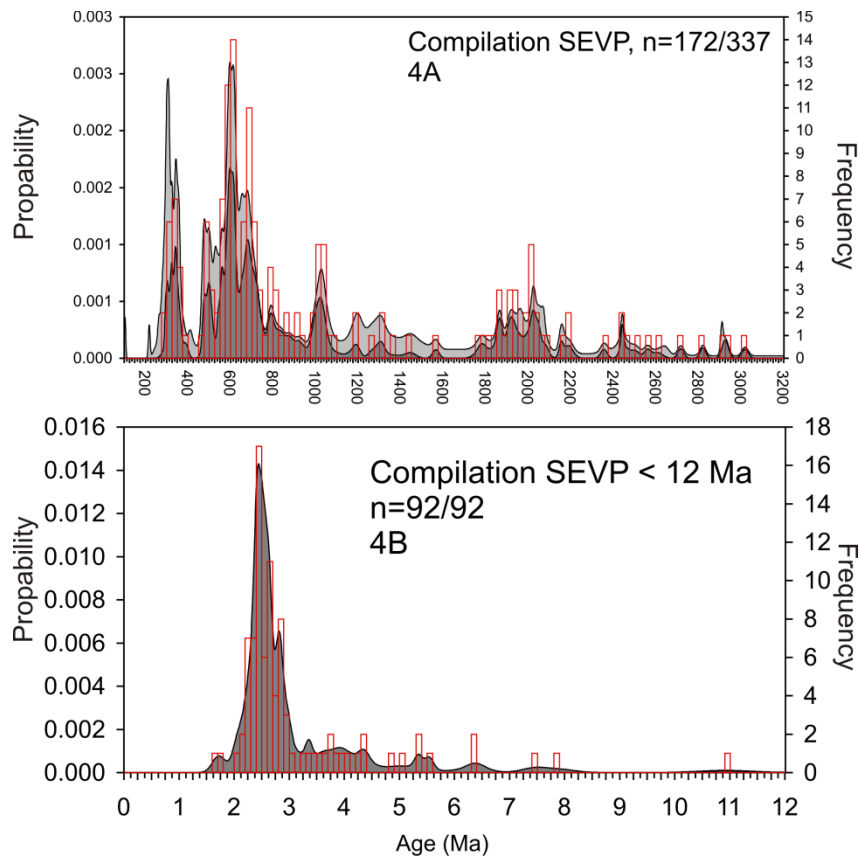

Fig.0.7: Zusammenstellung der U-Pb Daten aller drei Lokalitäten innerhalb der SEVP mit Altern > 100 Ma in (A) und Altern <12 Ma in (B).

Hf Isotopien in Kombination mit den entsprechenden U-Pb Altern zeigen 2 Krustenbildungstrends (Fig.0.8). Erste Krustenbildung fand im Archaikum statt und wurde anschließend recycled zwischen 2.5 und 1 Ga.

Der Zeitraum zwischen 1.0 und 1.5 Ga ist gekennzeichnet von juvenilem Krustenwachstum von einer verarmten Mantelquelle, die während der Kaledonischen und Variszischen Orogenese immer wieder recycled wurde. Zusätzlich scheint während der Zeit der Variszischen Orogenese der Mantel unterhalb der SEVP verarmt worden zu sein (siehe Kapitel 5). Nahezu vertikal angeordnete Datenpunkte im Bereich von etwa 0.5 bis 0.6 Ga deuten auf ein Krustenmischungsereignis in diesem Zeitraum hin.

Fig.0.8: Kombination der U-Pb Alter mit ihren entsprechenden Werten für  $\epsilon\text{Hf}(t)$  für Zirkone aus dieser Studie (grün) und Zirkone, publiziert von Abati et al. (2012) (schwarze Kästchen). Ein  $^{176}\text{Lu}/^{177}\text{Hf}$  Verhältnis von 0.0113 (Rudnick and Gao, 2003) wurde für die Berechnung der Krustenwachstumszonen benutzt. Werte für den verarmten Mantel stammen von Chauvel and Blichert-Toft (2001) und Vervoort et al. (1999).

Neogene Alter sind gekennzeichnet von fast chondritischen  $\epsilon\text{Hf}(t)$  Werten, die auf einen leicht verarmten Mantel als Quelle hinweisen. Jüngste Alter liegen bei etwa 2.6 Ma, mit oszillierender Zonierung und abgerundeten Kristallgrenzen der entsprechenden Zirkonkristalle. Diese Zirkone datieren das Alter der Eruption der Alkali Basalte, welches bereits zuvor durch K-Ar Datierungen bestimmt wurde von Bellon et al. (1983). Geringere Altersverteilungen zwischen 5 und 8 Ma bezeugen, dass die Extrusion von kalk-alkalischen Magmen, die generell weiter südwestlich aufgeschlossen sind (Turner et al., 1999; Duggen et al., 2003; Duggen et al., 2004), auch die SEVP beeinflusst haben.

Der Vergleich zu Studien von restitischen Einschlüssen eines Dacits und eines graphitischen Schiefers von Zeck und Williams (2002) und Zeck und Williams (2001) aus der Lokalität Cerro del Hoyazo und einer dazu nahegelegenen Lokalität, beide etwa 150 km Südwestlich von der SEVP entfernt, zeigt, dass die Altersverteilungen insgesamt sehr ähnlich sind. Diese Ähnlichkeiten weisen auf intensive Krustenstapelung innerhalb der Betischen Kordillere hin, da die Proben von Cerro del Hoyazo vermutlich aus größeren Tiefen entstammen.

Weitere Vergleiche zu Studien aus dem West Afrikanischen Kraton und des Arabisch-Nubischen Schildes (Abati et al, 2012; Avigad et al., 2012) zeigen, dass ein Großteil der hier analysierten Zirkone von den zuvor genannten Blöcken entstammen und während des Zusammenschlusses von Gondwana auf die Iberische Platte transportiert wurden.

## Summary

In this work we present new geochemical data about the evolution of mantle and crustal components in terms of their geochronological records and geochemical constraints. Two localities were chosen for this purpose. The Rehoboth Terrane in Namibia, with special regards to the Gibeon Kimberlite field and the south eastern volcanic province in Spain (SEVP), with special regards to the region around the small village of Casas de Tallante.

The Rehoboth Terrane is a tectonic domain of the southern African framework and due to its thick cover of sediments, not much is known about the composition, or the age of the underlying crust and mantle. A more detailed description of the regional geology can be found in chapter 3.3.

The SEVP is marked by different stadiums of volcanic activity from Neogene times. Knowledge about the deeper crust and the upper mantle with respect to time constraints is very rare. A broader overview about the geological setting is given in chapter 5.3.

Both areas are characterized by recent volcanic activity that has transported mantle and crustal xenoliths to the surface. These xenoliths and some other types of samples were subject for the work presented here. Samples collected in both areas were assumed to provide an insight into the evolution of the lower crust and upper mantle.

Regarding the mantle of both regions, major and trace elements of selected minerals (garnet, clinopyroxene, orthopyroxene, olivine) were measured by electron microprobe measurements and laser ablation ICPMS in order to determine the geochemical character, enrichment or depletion characteristics and pressure (P), temperature (T) relationships. Additionally, isotope systematics of the Lu-Hf (Namibia and Spain), Sm-Nd (Namibia and Spain) and Sr (Spain) isotope systems were determined by multicollector ICPMS in order to calculate the timing of mantle depletion and enrichment and to characterize mantle reservoirs.

For crustal samples, zircons were extracted from the crustal xenoliths (Namibia) and the debris of tuff layers (Namibia and Spain). The U-Th-Pb isotope systematics were determined by laser ablation ICPMS in order to get information about the age of crystallization. Additionally, Hf isotope analyses of the same zircon grains and the same growing domains were carried out by laser ablation multicollector ICPMS, providing information about the geochemical reservoir the zircons were derived from. Combining the ages as determined by U-Th-Pb isotope systematics

with Hf isotope systematics enabled us to see whether zircons are a product of juvenile crust formation and if the zircons analysed are related to each other in terms of crustal recycling or if crustal components with different isotopic characteristics were mixed (crustal mixing).

Finally, comparing the results about the makeup of the mantle and the crust provides the opportunity to make an assumption of how mantle and crustal processes were connected and if processes reflected in one domain can be seen in the other.

## **Evolution of the lower crust and the upper mantle of the Rehoboth Terrane**

### *Mantle*

We have investigated 19 mantle xenoliths (garnet peridotites) from the Gibeon Townlands and the Hanaus kimberlite pipes on the Gibeon kimberlite field that were transported to the surface by kimberlite eruptions 72.5 Ma ago (Davies et al., 2001). Major elements were determined for clinopyroxenes, garnets, olivine and orthopyroxenes and trace elements were analyzed in clinopyroxenes and garnets.

Most samples plot along a geothermal gradient of around 40 mW/m<sup>2</sup>, whereas a smaller number of samples are displaced to higher temperatures at same pressures. All samples are in the graphite stability field.

Rare earth element compositions of the garnets and clinopyroxenes suggest that the mantle beneath the Gibeon kimberlite field is made up of at least two different components (see Fig.0.1). The first type (type 'N') with 14 samples, has normal garnet REE patterns and Grt/(Grt+CPX) ratios of their modal abundance from around 0.5 to around 0.8. The second type (type 'σ') with only 5 samples, has sigmoidal garnet REE patterns with Grt/(Grt+CPX) ratios mostly around 0.99.

Fig.0.1 Type ‘N’ (A; blue) and type ‘σ’ (B; red) samples as determined by the REE patterns of corresponding clinopyroxenes and garnets. Concentrations are normalized to chondrite C1 (McDonough and Sun, 1995).

Lu-Hf isotope systematics of both types were determined by multicollector ICP-MS in order to calculate the timing of depletion from the corresponding mantle source. Sm-Nd isotope systematics of the same samples were obtained in a second step in order to determine the timing of enrichment by mantle metasomatism.

Trace element compositions of clinopyroxene and garnet normalized on a primitive sample from Vitim (Siberia) (Ionov et al., 2005), determined prior to isotope analyses, revealed that both isotope systems were affected by metasomatism for both types of samples. Therefore, ages calculated are regarded as to represent enrichment ages for both isotope systems.

Correlation of the Lu-Hf isotope systematics of four ‘N’ peridotites revealed a Proterozoic enrichment age of around 850 Ma from a slightly depleted mantle source ( $\epsilon\text{Hf}_{\text{initial}} = + 3.3$ ). Three samples with sigmoidal garnet patterns plot along an isochron with an age of around 1.9

Ga. The initial value of  $\epsilon_{\text{Hf}}^{\text{initial}} = + 29.4$  points towards a highly depleted mantle source (Fig.0.2).

Fig.0.2 Lu-Hf (A) and Sm-Nd (B) whole rock isotope systematics of type ‘N’ (blue) and type ‘σ’ (red) samples, showing a metasomatic overprint around 0.85 for the first and around 1.9 Ga for the latter. Sm-Nd isotope systematics of  $\sigma$  peridotites might point towards a late enrichment during the Pan African Orogeny.

Isotope systematics of Sm and Nd are scattered but three  $\sigma$  peridotites plot along an isochron with an age of around 450 Ma, suggesting metasomatic overprint during the Pan African Orogeny.

In addition, we have reinterpreted a previously published Re-Os dataset of garnet peridotites from the Louwrensia kimberlite pipe (Pearson et al., 2004), located within the Gibeon Kimberlite field. We propose an isochron being hidden in this dataset with an Archean age of around 2.9 Ga. The idea of an Archean component underneath the Rehoboth Terrane been envisaged before by different other authors (e.g. Hoal et al., 1995; Franz et al., 1996) and is supported by zircon ages from 2.7 to 2.9 Ga from our own works (see chapter 4) and as published by Cornell et al. (2011) and Van Schijndel et al. (2011). We interpret this age as the timing of depletion of the  $\sigma$  peridotites.

Our new results regarding the mantle underneath the Gibeon kimberlite field allows us to propose a revised geotectonical model as follows. We propose that by the time of the assembly of Eastern- and Western-block of the Kaapvaal Craton, fist mantle components of the Rehoboth

Terrane were created in the spinel stability field which were subsequently subducted underneath already existing crustal components and transformed into garnet peridotite. Collision of the Rehoboth Terrane with the Kaapvaal craton at around 1.9 Ga led to reenrichment of this mantle due to mantle metasomatism.

By the time of the Namaquan orogeny from 0.9 to 1.3 Ga, new mantle material was subducted beneath the Rehoboth Terrane and reenriched by mantle metasomatism at the end of this period at around 850 Ma. Final reenrichment may have occurred during the Pan African Orogeny at around 450 Ma.

### *Crust*

Additional determinations of the crystallization events in the lower crust beneath the Rehoboth Terrane in combination with the results of the enrichment events in the mantle should provide a better understanding about the tectonic events that have created the Terrane as is it nowadays.

We have analysed zircons of six carbonatite derived crustal xenoliths from the Gross Brukkaros Mountain as well as zircons from one crustal xenolith and from one sample of the kimberlite matrix of the Louwrensia Kimberlite pipe. Except for the matrix sample, all samples were high grade metamorphic rocks. After mineral separation, embedding and polishing, zircons were analyzed by Laser ablation ICPMS. Cathodoluminescence images of the zircons allowed precise age determinations of different growth domains within each zircon crystal. Depending on whether the zircons analysed stem from carbonatite or kimberlite derived crustal xenoliths, different age spectras are revealed (Fig.0.3).

Except for one sample, which contains younger zircons from the carbonatite itself, carbonatite derived xenoliths have age peaks mainly between 1.0 and 1.5 Ga, whereas zircons from kimberlite derived samples range from about 0.6 Ga up to 2.9 Ga, with major age peaks around 1.1 to 1.2 and 1.8 to 1.9 Ga. The matrix sample shows a much broader range of ages, from around 0.5 to 2.9 Ga, whereas younger ages can be the result of zircons derived from the Nama shales.

Fig.0.3 U-Pb age spectras for kimberlite and carbonatite derived samples from the Gibeon Kimberlite field and carbonatite vents close to the Gross Brukkaros Mountain.

Additional Hf isotope analyses of the same zircons on top or next to the U-Pb laserspots but in the same growing domain yielded more information about the source of the crust. Combined with the results of the U-Pb analyses, they can reveal crust formation, recycling or mixing events.

Fig.0.4 Hf isotope systematics of the zircons from Gibeon and around the Gross Brukkaros Mountain combined with the corresponding U-Pb ages, marking four episodes of juvenile crust generation, with subsequent crust recycling and crustal mixing trends. Trends were calculated with a  $^{176}\text{Lu}/^{177}\text{Hf}$  of 0.0113 (Rudnick and Gao, 2003).  $^{176}\text{Hf}/^{177}\text{Hf}$  values for the depleted mantle are taken from Chauvel and Blichert-Toft (2001) and Vervoort et al. (1999).

With respect to these events, there are four phases of crustal growth from a depleted mantle source within the dataset (Fig.0.4).

First crustal growth is recorded in the Archean at around 2.7 to 2.9 Ga from a primitive mantle source or from a depleted mantle source with model ages from 3.05 to 3.38 Ga.

Juvenile crust was formed between 2.3 and 2.7 Ga from a depleted mantle source with subsequent recycling until 1.0 to 1.2 Ga.

The timespan between 1.5 to 1.6 Ga marks the next time of juvenile crust formation from a depleted mantle source and intensive crustal recycling until around 1.1 Ga and crustal mixing between 1.3 and 1.1 Ga. Mostly positive  $\epsilon\text{Hf}(t)$  values are characteristic for the timespan between 1.3 to 1.5 Ga. About 60 % of all data points plot in the range between 1.0 to 1.4 Ga.

The youngest crust forming event ranges from 0.8 to 1.1 Ga with subsequent recycling during the Pan African Orogeny at around 0.5 to 0.6 Ga.

The sample, derived from the matrix of the louwrensia kimberlite pipe shows a much higher variation in ages and Hf isotope systematics than all other samples. This is probably related to the fact that zircons from the Nama shales are incorporated in this sample.

Considering the different age spectras of kimberlite and carbonatite derived samples, slightly different stratigraphic units must have been sampled.

This part of the study has shown that the crust beneath the Gibeon Kimberlite field is made up of metamorphosed sediments. Without considering the ages that probably stem from zircons from Nama shale sediments, youngest ages are in the range of about 0.9 Ga.

Oldest crust was probably generated in the Archean, followed by an episode between 1.8 and 1.9 Ga in which the Rehoboth Terrane has been attached to the Kaapvaal Craton. The latter event is also recorded in the geochronological record of the mantle xenoliths from Gibeon as an enrichment event of the  $\sigma$  peridotites (see chapter 3).

Subduction beneath the Kalahari plate is probably the cause for crust generation, recycling and mixing during a timespan between 1.5 and 1.1 Ga with around 60 % of all datapoints of this study lying in this range and has first been proposed by (Becker et al., 2006).

The Namaquan Orogeny also affected the crust beneath the Gibeon Kimberlite field by forming juvenile crust from a depleted mantle source that was subsequently recycled during the Pan African Orogeny. The Namaquan orogeny is reflected by the addition of new mantle components ('N' peridotites) and their subsequent enrichment. A late Pan African overprint is also reflected in the Sm-Nd isotope systematics of the  $\sigma$  peridotites (see chapter 3).

## **The lower crust and the upper mantle of the South eastern volcanic province in Spain**

### *Mantle*

Spinel / Plagioclase peridotites from the neogene alkaline basaltic volcano Cabezo Negro de Tallante were collected and selected minerals from 11 samples were separated. Plagioclase could

only be found in 5 samples. Major and trace elements of clinopyroxenes and orthopyroxenes, as well as major element for olivines and plagioclases (if available) were measured by the electron microprobe and laser ablation ICPMS. Seven samples were chosen for isotope analyses, specifically the Lu-Hf, Sm-Nd and Rb-Sr isotope systems.

All samples chosen stem from pressure ranges between 7 to 20 kbar and temperature ranges between 900 and 1000°C as determined by the two pyroxene thermometer of Brey and Koehler (1990) and the Ca in olivine barometer of Koehler and Brey (1990).

Fig.0.5 Three types of samples for the Spinel / Plagioclase peridotites from Cabezo Negro de Tallante as determined by the REE patterns of the corresponding clinopyroxenes, normalized to C1 (McDonough and Sun, 1995). Type 1 is marked in green, whereas type 2 is marked in red and type 3 is marked in blue.

Based on the trace element concentrations, three different types of patterns could be differentiated. Type one is characterized by slightly enriched middle rare earth elements (MREE), and slightly depleted light rare earth elements (LREE) relative to the MREE (see Fig.0.5 - green). Type two shows almost flat rare earth element patterns and lower contents of

REE in general compared to type one (see Fig.0.5 - red). Type three consists of only one sample that is highly enriched in LREE, whereas the corresponding MREE and heavy rare earth elements (HREE) are mostly following the patterns of type 1 (see Fig.0.5 - blue).

Normalization on a primitive sample from Vitim Siberia (Ionov et al., 2005) shows enrichment of LREE for all 3 types of samples.

Fig.0.6 A possible depletion event might have occurred at a time around 550 Ma, as interpreted from Lu-Hf isotope systematics of three samples from this dataset and an additional sample as published by Bianchini et al. (2011) and Beccaluva et al. (2004).

Lu-Hf isotope systematics of all samples measured do not show a clear correlation due to a small  $^{176}\text{Lu}/^{177}\text{Hf}$  range and some scatter. However, including one additional sample (TL16) from the same locality that was published earlier (Beccaluva et al., 2004; Bianchini et al., 2011), four datapoints can be correlated to an age at around 550 Ma (Fig.0.6). As Hf seems to be

untouched by enrichment events, this age could be a possible age of depletion for the mantle underneath the SEVP. Model ages of two additional samples point towards an older component being present underneath the SEVP, which is in accordance with the isotope studies of Tallante xenoliths by Bianchini et al. (2011) and the comparison to other localities in Europe (Downes and Dupuy, 1987; Reisberg et al., 1989; Bodinier et al., 1991; Downes et al., 1991; Zangana et al., 1997; Beccaluva et al., 2001; Downes et al., 2002).

Sm-Nd isotope systematics cannot be associated in an isochron, but the datapoints scatter around a projection of 550 Ma.

Sr isotope systematics of clinopyroxene and plagioclase mostly differ, with higher  $^{87}\text{Sr}/^{86}\text{Sr}$  isotope ratios for the plagioclase in comparison to the clinopyroxenes. The first are probably the result of a metasomatic overprint while in contact with the alkaline basaltic melts, while the latter seem to have remained untouched by this event.

### *Crust*

Three samples from alkali basaltic outcrops within the SEVP were collected in order to decipher the evolution of the corresponding lower crust. These samples were either taken from tuff layers (CNTS-1 and ALCS-1) or the matrix of the alkali basalts (CG-Z1 – CG-Z3).

Sieving of the samples in the field was followed by heavy liquid separation, magnetic separation, treatment with 6M HCl, sieving with one-time fabric sieves and handpicking with the use of a stereomicroscope.

Growing domains within the zircons crystals were revealed by cathodoluminescence images and U-Th-Pb isotope ratios of homogenous domains were determined by laser ablation ICPMS. In a later step, Hf isotope compositions were determined by laser ablation multicollector ICPMS. By combining the information obtained from both methods it was possible to obtain a better understanding of how the crust beneath the SEVP developed in terms of juvenile crust generation, crustal recycling and crustal mixing.

Fig.0.7 A compilation of the U-Pb data of all three localities within the SEVP with ages > 100 Ma shown in (A) and ages < 12 Ma as shown in (B).

All three samples show very similar age patterns, with a wide range from around 2.6 Ma up to 3 Ga. Main age distributions are between 0.3 to 0.4, 0.5 Ga and 0.6 to 0.7 Ga. Some minor age distributions are between 1 Ga to 1.1 Ga, 1.8 to 2.2 Ga, 2.4 to 2.6 Ga and 2.9 to 3 Ga (Fig.0.7).

Hf isotope systematics in combination with the U-Pb ages revealed two major crustal development trends (Fig.0.8). First crust was formed during the Archean and was subsequently recycled between 2.5 to 1 Ga. In a timespan between 1.0 to 1.5 Ga, new crust was generated from a depleted mantle source, which was constantly recycled during the Caledonian and Variscian orogenies. The latter might be reflected in a depletion event in the mantle (see chapter 5). Additionally, a vertical array of datapoints points to a crustal mixing event at a time around 0.5 to 0.6 Ga.

Fig.0.8 Combination of U-Pb and corresponding  $\epsilon\text{Hf}(t)$  values for the zircons from this study (green) and from Abati et al. (2012), marked as black squares. A  $^{176}\text{Lu}/^{177}\text{Hf}$  of 0.0113 (Rudnick and Gao, 2003) was used for the calculation of the fields of crustal growth. Values for the depleted mantle are from Chauvel and Blichert-Toft (2001) and Vervoort et al. (1999).

Neogene ages have  $\epsilon\text{Hf}(t)$  values that are nearly chondritic, indicating a slightly depleted mantle as the source of melt extraction. The most recent ages amongst these are around 2.6 Ma with oscillatory zoning and subrounded edges of the corresponding zircon crystals. They record the timing of when the alkali basalts erupted to the surface as determined previously by K-Ar (Bellon et al., 1983). Minor age distributions around 5 to 8 Ma, indicate that the extrusion of calc-alkaline magmas that are generally be found further southwest of the SEVP (Turner et al., 1999; Duggen et al., 2003; Duggen et al., 2004) have affected the SEVP as well.

The comparison to previously published data of restitic enclaves of a dacite and a graphitic schist from Zeck and Williams (2002) and Zeck and Williams (2001) of Cerro del Hoyazo and another nearby locality around 150 km further Southwest in the Betic Cordillera of Cabezo Negro de Tallante, show that the age patterns are very similar. These similiarities in ages suggest a stacking of nappes within the Betic cordillera as the samples from Cerro del Hoyazo are probably derived from greater depths.

Further comparisons to studies from the West African Craton and the Arabian-Nubian shield (Abati et al, 2012; Avigad et al., 2012) suggest that a major part of the zircons are derived from these blocks and were transported onto Iberia during the assembly of Gondwana.

## Chapter 1: Introduction

The formation of the continental crust and the lithospheric mantle is a topic of high significance in geo sciences and the geochronological aspects of this process are still unknown for larger areas of the earth. Despite years of research, there is no clear agreement of how the generation of crustal portions and its corresponding underlying mantle are associated with each other. The theory of pulsed growth is in direct contrast to the steady accumulation of continental crust as summarized by Pearson et al. (2007).

In this work, we try to bring new light into the discussion through the investigation of crustal and mantle material with the comparison between two distinct localities in Namibia and the southeastern volcanic province in Spain. These localities were chosen as they enable direct access to sample material that was transported by the ascent of kimberlitic and carbonatitic (Namibia) or basaltic melts (Spain). Furthermore there is a lack of data regarding the crustal and mantle processes that happened in the past for both study areas. It is still unknown how the Rehoboth Terrane fits into the southern African framework with respect to its geochronological past. Despite numerous investigations of mantle xenoliths from Cabezo Negro de Tallante in the South eastern volcanic Province (SEVP), no information about depletion or enrichment processes is available from that area, as well as no information about the evolution of the deeper crust.

The comparison of the geochronological records from both study areas as well as major and trace element budgets should give direct information about the coherency between mantle and crustal development. The questions of when, how often and in what geothermobarometrical regime the mantle was depleted and enriched as well as the question of when crustal material crystallized from which sources are subject of this study.

Since the routine usage of laser ablation ICP mass spectrometry in the last years, the determination of geochronological records of crustal material has increased dramatically (e.g. Fryer et al., 1993; Hirata and Nesbitt, 1995; Scott and Gauthier, 1996; Gerdes and Zeh, 2006; Zeh and Gerdes, 2010; Avigad et al., 2012). The analysis of the accessory mineral zircon, which can be found in most crustal rocks, for U-Pb isotope systematic allows a precise determination of the age of crustal crystallization. Additionally, Hf isotope ratios of the same mineral grains give information about the source of melt extraction.

Age determination of mantle material, specifically of garnet and spinel peridotites, requires a much more extensive sample preparation. In this work, we have analyzed our samples for Lu-Hf (Namibia and Spain) and Sm-Nd (Namibia and Spain) and Sr (Spain) isotope systematics by isotope dilution multicollector ICP mass spectrometry. Lu-Hf can thereby provide information about the timing of mantle depletion, Sm-Nd and Sr isotope measurements, however, show great potential for giving information about the enrichment of mantle portions due to mantle metasomatism by the interaction with fluids.

### **1.1. Determination of mantle depletion ages**

The conventional method of determining mantle depletion ages/the age of melt extraction, is Re-Os isotope measurements, of, in most cases, whole rock samples of peridotites (e.g. Hoal et al., 1995; Pearson et al., 2004; Rudnick and Walker, 2009). The basic assumption hereby is that during melt extraction, all Re is extracted into the melt and that Re/Os ratios in the residue are zero. This however is only the case for high degrees of partial melting which is true for most cratonic areas, such as the Kaapvaal craton, but has turned out to be much lower in the surrounding Proterozoic mobile belts, such as the Namaqua Natal belt in southern Africa. As the derivation of an isochron for Re-Os is very difficult, model ages are usually determined by calculating of Rhenium depletion ( $T_{RD}$ ) or Rhenium model ages ( $T_{MA}$ ). If during melt extraction all Re has been driven off into the melt, no radiogenic  $^{187}\text{Os}$  can be formed in the residue since this event. If however some Re was still in the residue after melt extraction, the  $^{187}\text{Os}/^{188}\text{Os}$  ratio increases and the  $T_{RD}$  age only represent a minimum age. In contrast,  $T_{MA}$  ages represent a maximum age. Due to the uncertainty of the concentration of Re in the residue after melt extraction and the uncertainty of the initial chondritic  $^{187}\text{Os}/^{188}\text{Os}$  isotope ratio, ages determined by the methods mentioned before are afflicted by a certain factor of uncertainty.

Another potential way of determining the timing of mantle depletion is the application of the Lu-Hf isotope system. In contrast to the Re-Os isotope system, during melt extraction, the daughter element Hf is extracted into the melt. It has become more and more popular in the last years as it appeared to be more robust to a metasomatic overprint compared to other isotopic systems (e.g. Schmidt et al., 2008; Lazarov et al., 2009). This means that the information about the age of mantle depletion is still preserved in the residue. In this study we analyze garnet and

clinopyroxenes as they carry the major amount of Hf in their crystal lattice with respect to all other coexisting phases in garnet, spinel, and plagioclase peridotites. The initial value of an isochron derived from clinopyroxenes in the spinel field or from bulk rocks calculated from the modal amounts of clinopyroxenes and garnets, gives additional information about the source of melt extraction, specifically if the source was the depleted or primitive mantle, i.e. if the source has experienced earlier melt extraction. We find, however, that Hf is commonly also reintroduced in small amounts and that it appears to date a first metasomatic overprint (which may also be the trigger of renewed partial melting) more accurately.

### **1.2. Determination of metasomatic overprint in the mantle**

After melt extraction from a mantle source of whatever nature, trace elements carrying fluids with high concentrations of the more incompatible elements like the light rare earth elements can overprint the residue again. The age dating of such overprints should yield the most accurate results with the radiogenic Sm-Nd or the Rb-Sr isotope systems. After enrichment with the specific elements, the geochronological clock is reset and starts to tick again from the time of enrichment. Given enough time to reequilibrate, isochron ages can be determined, resulting in the age of enrichment. If, however, multiple enrichments occur at different times, the age of mantle metasomatism can no longer be deciphered for the individual events.

### **1.3. The age of crystallization of the continental crust**

As mentioned earlier, the accessory mineral phase zircon is most suitable to determine crustal ages and crustal growth. Until the advent of SIMS (Secondary Ion Mass Spectrometry) and Laser Ablation Inductively Coupled Mass Spectrometry (LA ICPMS), this was carried out by dissolving individual or pooled zircons and measuring the U and Pb isotope systems by Thermo ionization mass spectrometry (TIMS). The introduction of LA ICPMS has dramatically simplified the analysis of zircons (at a cost of accuracy compared to TIMS). The huge advantage compared to TIMS is the possibility to analyse single domains in individual zircons (which were previously characterized by cathodoluminescence) and the much higher sample throughput compared to SIMS.

LA ICPMS has therefore become the most popular method to determine the age of crystallization in zircon grains since its beginning in the early 1990's (e.g. Fryer et al., 1993). U has a similar ionic radius as zirconium and can therefore easily replace the zirconium within the crystal lattice. In contrast, almost no Pb fits into the lattice due to its higher ionic radius. The Pb in the zircons is therefore almost exclusively radiogenic and general, only very small corrections have to be made for common lead ( $^{204}\text{Pb}$ ). Much more information can be hidden in the zircon crystal, such as a later phase of metamorphism, during which zircon can have added another rim domain, surrounding the older core. The analysis of these domains can, for example, reveal the timing of metamorphism in connection with regional orogeny events.

The information about the age of crystallization alone does not necessarily allow the prediction of genetical relationships of different crustal components. Such relationships can be further explored from the combination with the analysis of Hafnium isotope composition by LA ICPMS on the same spots which will give further information on the nature of crustal melt extraction and crustal development trends. It shows, based on average  $^{176}\text{Lu}/^{177}\text{Hf}$  contents of a hypothetical crust, if zircon ages are cogenetic on the same trend for crustal development or if crustal components have been mixed and were isotopically homogenized.

#### **1.4. Goals of this study**

- A. Determination of mantle depletion and enrichment processes as well as geothermobarometrical constraints underneath the Gibeon Kimberlite Field / the Rehoboth Terrane using by major, trace element and isotope (Lu-Hf, Sm-Nd) data.
- B. Determination of crustal forming or recrystallization events of the deeper crust of the Rehoboth Terrane by U-Pb isotope measurements of zircons that stem from crustal xenoliths. These results shall be compared to the results of 1.4.A..
- C. Determination of mantle depletion and enrichment processes in the South Eastern Volcanic Province (SEVP) as well as the determination of the thermobarometric regime of the spinel / plagioclase peridotites by major, trace element and isotope measurements of the constituent minerals.

- D. Deciphering the crust forming events beneath the SEVP by U-Pb and Hf isotope analyses of zircons from crustal debris available from tuff layers that are associated with Neogene alkaline basaltic volcanism of southeastern Spain. Comparison to the results of 1.4.C.

## **Chapter 2: Methodology**

### **2.1. Sample crushing - SelFrag®**

As a first separation step, hand specimens were crushed with a SelFrag® fragmentation system. Using this technique allows a clean separation of the samples along the grain boundaries with a highly reduced risk of cross contamination. In contrast to conventional techniques (e.g. jaw crusher), the sample is placed into a vessel filled with tap- or deionized water. Two electrodes are placed face to face, with the sample in between in the vessel. A built-in sieve with a mesh size of 1 mm separates two compartments within the vessel. The distance between these electrodes can be adjusted from 40 to 10 mm. The sample is processed by electrical pulses with high voltage currents, starting from 90 KV up to 200 KV and frequencies from 1 to 5 Hz. Thereby currents run through the sample, following grain boundaries. Electrical discharges within the sample crush the sample as they are converted into acoustical shockwaves.

Depending on the constitution of the sample, pulse rates for crushing a sample in hand specimen size range from 50 to 200 pulses.

As all parts of the machine and the vessel can be rinsed with water, and the risk of remaining particles is practically nil and cross contamination does not occur.

### **2.2. Major element analyses**

Major elements were determined by wavelength dispersive analyses with a Jeol JXA 8900RL Superprobe with five spectrometers, each of which contains several crystals for quantitative analyses. In general, sample mounts or thick sections were polished and cleaned with benzine (p.a.) before drying in a vacuum oven at 50°C for several hours. After drying down, samples were carbon coated with a Jeol JEE4B coating system. Samples were built into the microprobe under high vacuum conditions ( $10^{-6}$  mbar). Acceleration voltage was adjusted to 15 kV and a 3 µm beam with a current of 20 nA was chosen. Measuring times for element peaks was adjusted from 20 to 30 s, while background measurement times were from 10 to 30 s.

For the determination of Ca in olivine (see Chapter 5), peak and background measurement times were increased to 120 s, in order to lower the detection limit of Ca.

Standards were either mineral standards, pure oxides or metals. For the determination of Ca in olivine, standard SCKA, as described in Koehler and Brey (1990), was used for calibration.

Where ever possible, multiple analyses on each grain were performed.

For all measurements, matrix corrections were carried out using the CITZAF© algorithm by John T. Armstrong.

### **2.3. Trace Element analyses**

Trace element analyses were carried out with a Thermo-Finnigan® Element 2 inductively coupled plasma mass spectrometer coupled to either a Resonetics M50 laser ablation system or a New Wave Research® UP213 ultraviolet Nd-YAG laser. Aluminum sample and skimmer cones were used throughout the analytical sessions. The same sample mounts or thick sections used for major element analyses were used here.

Before each session, the mass spectrometer was tuned to maximum signal yield and minimum oxide formation rate by line scans on standard Nist 612.

Samples were ablated with 40 µm spots, laser energies of around 0.6 mJ and a frequency of 10 Hz with several spots on each grain. External standardization was performed, using a Nist 612 glass standard, combined with CaO concentrations as determined earlier by electron microprobe measurements. Precision of the analyses as well as machine conditions were checked by analyzing USGS standard Bir-1G at the beginning and the end of a session as well as in between.

Raw data was processed with the Gemoc GLITTER© software, using reference values for CaO from Pearce et al. (1997).

### **2.4. Isotope analyses**

#### **2.4.1. Chromatographic separation**

Low concentrations of Lu, Hf, Sm, Nd and Sr and high interference with isotopes of other elements makes a direct in-situ measurement by Laser Ablation ICP mass spectrometry not possible for our mantle derived samples. In order to increase the amount of the desired elements, chromatographic separation was a first step prior to analysis. This was performed in several laboratory sessions ('batch') in a PicoTrace clean laboratory at the Goethe University Frankfurt

am Main. After the separation of the garnet- or spinel xenoliths with SelFrag®, heavy liquid separation, magnetic separation, sieving, handpicking under a microscope and leaching with 6 M HCl on a hot plate, mineral separates of clinopyroxene and garnet were ultrasonicated in Milli-Q water for at least 1 hour and then rinsed with Milli-Q® water again. These steps were followed by weighing in each sample and spiking separately with a  $^{176}\text{Lu}$ - $^{180}\text{Hf}$  and  $^{149}\text{Sm}$ - $^{150}\text{Nd}$  spike solution. For each sample batch, standard BCR-1 and a blank were performed to assure that no isotope fractionation has occurred during separation as well as that no contamination came from performing the separation or the resin itself. Subsequent dissolution of the samples was carried out with either a 2:1 HF (24 M)  $\text{HNO}_3$  (15 M) solution or a 3:1 HF (24 M)  $\text{HNO}_3$  (15 M) acid mixture in closed Savillex® Teflon beakers at 120°C.

After a three day treatment with a 2:1 HF  $\text{HNO}_3$  solution, samples were dried down with open lids at 120°C. From here, sample cakes were treated variantly with 6 M HCl and 6 M  $\text{HNO}_3$  overnight and then fumed off.  $\text{HNO}_3$  was used in order to break down fluorides. After these steps, full dissolution was achieved.

Another fraction of the samples was dissolved in a 3:1 HF  $\text{HNO}_3$  acid solution for 24 hours at 120°C in closed Savillex® Teflon beakers. 150  $\mu\text{L}$  of perchloric acid was added in each beaker before the evaporation of the acid mixture at 120°C with the lids removed from the beakers. Perchloric acid was added in order to prevent fluorides to be formed, which was subsequently evaporated at 180°C.

After drying down, the sample cake was redissolved in 3 M HCl, together with 0.1 M ascorbic acid ( $\text{C}_6\text{H}_8\text{O}_6$ ) in order to reduce  $\text{Fe}^{3+}$  to  $\text{Fe}^{2+}$  as otherwise the resin in the column might be blocked (Muenker et al., 2001).

Before loading the columns, all samples were centrifuged in order to avoid loading the columns with possible inclusions that were remaining in the dissolved mineral grains.

Chromatographic separation of Lu and Hf followed the procedures of Muenker et al. (2001) using 1 mL Teflon columns, filled with Eichrom® Ln.Spec resin. The zirconium washing step was omitted as the concentrations of Hf in the individual samples were extremely low and a possible loss of Hf would have been crucial to the following measurements with the mass spectrometer. Hf was collected using 2 M HF instead of 6 M HCl with 0.2 M HF as proposed by Muenker et al. (2001).

The matrix collected in the first step was dried down at 120°C for each sample, redissolved in 2 M HCl and loaded on 1.5 mL Teflon columns, filled with Biorad 50Wx8 resin. The separation of LREE from the matrix with 6 M HCl and of Sm and Nd followed the procedures of Pin and Zalduegui (1997) and the separation of Sr with 2.2 M HCl as taken from ((Lazarov, Unpublished results) PhD thesis).

Using exactly the same columns as for the separation of Lu and Hf, Sm and Nd were eluted with 0.75 M HCl and 0.25 M HCl respectively in the Eichrom® Ln.Spec resin.

All elements to be measured with the mass spectrometer were dried down at 120°C and redissolved in 2% HNO<sub>3</sub>.

#### **2.4.1. Isotope analyses solution (Lu-Hf, Sm-Nd, Rb-Sr)**

After calibration of the machine to highest level of sensitivity of the desired element, samples were measured, using a Thermo-Finnigan® Neptune multicollector ICPMS at the Goethe University in Frankfurt. Ni X cones were used and measurements were performed following the procedures of Schmidt et al. (2008). To increase the sensitivity for Lu and Hf measurements, a CETAC Aridus™ nebulization system (ca. 70 µL/min; e.g., Hf, 500-800 Vppm<sup>-1</sup>) was used instead of a conventional glass spray chamber. For Sm-Nd and Rb-Sr, a conventional glass spray chamber was used for the introduction of the sample.

JMC 475, Merck, Ames, Mir a (Rankenburg et al., 2004) and inhouse standards were used for tuning the mass spectrometer and for checking measurement conditions. BCR-1 was measured during each analytical session in order to assure perfect conditions for the previous chromatographic separation.

Mass bias correction was performed with 0.7325 for <sup>179</sup>Hf/<sup>177</sup>Hf and 0.7219 for <sup>143</sup>Nd/<sup>144</sup>Nd (Blichert-Toft et al., 1997). Interference correction of <sup>176</sup>Lu and <sup>176</sup>Yb was monitored with a <sup>173</sup>Yb/<sup>171</sup>Yb ratio of 1.1248. For samples with very low amounts of Hf, a blank correction was performed.

Data was evaluated using Excel® in-house spreadsheets and subsequent age calculations, using Isoplot 3.7 (Ludwig, 2008).

#### **2.4.2. Isotope analyses laser ablation (U-Pb, Lu-Hf)**

After the separation steps, zircons crystals were embedded onto round epoxy holders with a diameter of 1 inch, polished and coated with gold. Cathodoluminescence (CL) images of each grain were necessary as a preliminary work for the subsequent analyses with the mass spectrometer as they reveal the growing patterns of the crystals. Before starting isotope measurements, gold coating was removed and the sample mounts were cleaned with ultrapure Ethanol and low concentration (2 %) ultrapure nitric acid.

U-Pb and Hf analyses for crustal sample material from Spain were performed using a New Wave Research® UP213 ultraviolet Nd-YAG laser with spot sizes varying between 20 and 40  $\mu\text{m}$  and Ni X skimmer and Al sample cones. Zircons from Namibia were analyzed for U-Th-Pb and Hf isotopes with the help of a Resonetics M-50 laser ablation system. Spot sizes hereby varied between 20 to 33  $\mu\text{m}$  with laser energies around 90 to 100 mJ. Before starting the measurement, samples were preablated with three shots of the same laser energy as used for the subsequent measurement in order to remove possible surface contamination. Measurements were performed on a Thermo-Finnigan® Element 2 mass spectrometer that was tuned to maximum signal and low oxidation rate prior to analysis, ablating GJ1 reference standards in line scans.

Independent from the laser used, U-Pb analyses were performed following the procedures as described by Gerdes and Zeh (2006). Laser spots were placed on homogenous growth sections of each zircon crystal with the help of CL images. Standard GJ1 was measured repeatedly before, in between and at the end of each analytical session. Additionally, Plešovice (see Slama et al., 2008) was measured as a secondary external standard to assure ideal machine conditions.

Data was evaluated using Excel® in-house spreadsheets created by A. Gerdes. Concordia diagrams were created, using Isoplot 3.7 (Ludwig, 2008). Age probability-density diagrams were created, using the Excel® spreadsheet of Sircombe (2004).

Hf isotope analyses were performed using the laser systems mentioned before, connected to a Thermo-Finnigan® Neptune multicollector ICP mass spectrometer. Additional laser spots were placed on top of the craters remaining from the U-Pb measurements of the zircons grains. As for the Hf isotope solution measurements, a CETAC Aridus™ nebulization system was used instead of a conventional glass spray chamber for signal enhancement. Standard solution JMC 475 was

used to tune the mass spectrometer to maximum signal yield while standards GJ1 and Plešovice were used as secondary standards.

Analyses followed the procedures as described by Gerdes and Zeh (2006). Evaluation of the raw data was performed using Excel® in-house spreadsheets by A. Gerdes.

## Chapter 3:

### **The lithospheric mantle underneath the Gibeon Kimberlite field (Namibia): a mix of old and young components - evidence from Lu-Hf and Sm-Nd isotope systematics**

T. Luchs\*, G. P. Brey, A. Gerdes, H.E.Hoefler

Institut für Geowissenschaften, J.W. Goethe-Universität, Altenhöferallee 1, D-60438 Frankfurt am Main, Germany

Submitted to Precambrian Research 18/04/2012

#### **3.1. Abstract**

We have determined major and trace elements and the Sm-Nd and Lu-Hf isotope systematics in minerals of 19 garnet peridotites from the Gibeon Townlands and Hanaus kimberlite pipes. These are situated within the mixed age Proterozoic to Archean (?) Rehoboth crustal province in Namibia. Our geothermobarometric results confirm the similarities of the conductive geothermal gradients underneath the Rehoboth province and the Kaapvaal craton and also that the Rehoboth mantle must have lost a significant proportion of its lithosphere. We distinguish peridotites with sigmoidal REE patterns similar as they commonly occur in the Archean Kaapvaal subcratonic mantle and peridotites with LREE depleted patterns typical for the Proterozoic. Both types are re-enriched restites with a kinship of processes in the sigmoidal ( $\sigma$ ) peridotites with the Archean (higher degrees of partial melting, style of re-enrichment). Time constraints for these processes can be found from the Sm-Nd and Lu-Hf isotope systems and from published Re-Os data. The Lu-Hf isotope systematics date an enrichment event of a highly depleted mantle ( $\epsilon_{\text{Hf}} = +29.4$ ) for the  $\sigma$ -peridotites of around 1.9 Ga ago. Enrichment for the N-peridotites occurred around 850 Ma ago in a slightly depleted mantle ( $\epsilon_{\text{Hf}} = +3.3$ ). The last enrichment event at around 458 Ma may be recorded by the Sm-Nd system in the  $\sigma$ -peridotites. published Re-Os isotope data set from the neighbouring Louwrensia pipe yields oldest, probably realistic Archean Rhenium model ages of 2.65 Ga (calculated for a Primitive Upper Mantle model). Archean mantle ages

underneath the Rehoboth crust are in accord with recently published zircon ages between 2.7 and 2.9 Ga from cobbles in tillites and from our own sampling of zircons in the Louwrensia pipe.

### 3.2. Introduction

Recent comparative work on mantle samples from on- and off-craton localities from Southern Africa (Bell et al., 2003; Janney et al., 2010; Mather et al., 2011) has shown that distinct differences but also strong similarities exist between mantle xenoliths from beneath the Kaapvaal craton and the Proterozoic terranes (for which most information comes from the Gibeon province in Namibia). Differences are expressed i) in higher average forsterite in olivine and lower Al<sub>2</sub>O<sub>3</sub> and CaO whole rock concentrations of the Archean mantle indicating higher degrees of depletion, ii) in differing depletion ages with very unradiogenic <sup>187</sup>Os/<sup>188</sup>Os indicating extensive melt depletion before 2.5 Ga in the ‘Archean’ mantle compared to a wider range and higher Os isotope ratios in the ‘Proterozoic’ mantle. The latter indicate lower degrees of partial melting possibly with incomplete removal of Re from the residue and give Re-depletion ages less than 2.2 Ga [Janney et al. (2010) and earlier work] and iii) in the lithosphere thickness which is thinner underneath the Proterozoic terranes by 30 – 40 km (see also Boyd et al. (2004) and Muller et al. (2009)). Similarities exist a) in the conductive limbs of the geothermal gradients indicating similar lithospheric thicknesses sometime in the past (see also Boyd et al. (2004), Franz et al. (1996a) and Mitchell (1984)), b) with respect to the overabundance of orthopyroxene in the mantle samples [less pronounced in the residual peridotites from Gibeon than from the Kaapvaal craton -see also Boyd et al. (2004) and Franz et al. (1996b), and c) in the existence of garnets with sigmoidal REE patterns. These are common amongst Kaapvaal peridotites but also occur as a minor proportion in the Gibeon (see below) and Rietfontein area [2 out 10 samples in the latter; see Hoal et al. (1994)].

Franz et al. (1996b) suggested that the orthopyroxene enriched peridotites from the Gibeon province represent pieces of the Kaapvaal lithosphere, which were rifted underneath the Rehoboth Terrane in the wake of the Atlantic ocean opening or that the Kaapvaal lithosphere extended underneath the Rehoboth Terrane. Both models were rendered unlikely by (Boyd et al., 2004; Pearson et al., 2004) because the oldest T<sub>RD</sub> age from peridotites of the Gibeon province is

2.1 Ga. This argument is only valid if Re is completely removed from the residue at very high degrees of partial melting, so that  $T_{RD}$  ages date the depletion event. Otherwise, these ages are only minimum ages. Alternatively, depletion ages younger than the Archean may indicate that the thermal regime in a cooling Earth may have been still high enough in the Proterozoic to produce relatively high degrees of partial melting; orthopyroxene enrichment was produced by some process like it occurred in the Archean. These mantle portions were later juxtaposed to or injected by less depleted mantle material. We have set out to clarify these questions by creating and evaluating an extensive major and trace element and Sm-Nd and Lu-Hf isotope data set on minerals from peridotite xenoliths from the Hanaus and Gibeon Townlands kimberlite pipe in Namibia. These could give supplementary answers to the Re-Os isotope data from the neighbouring Louwrensia kimberlite pipe or enable a more comprehensive interpretation of these data. We assume in our approach that clinopyroxene and garnet carry almost the entire incompatible trace element inventory of the rock and that their analysis combined with the mineral proportions gives the bulk rock major, trace and Sm-Nd and Lu-Hf isotope composition.

### **3.3. Geological setting and previous work**

The Gibeon Kimberlite Province is located in Namibia between Keetmanshoop and Mariental on the border of the mid Proterozoic to Archean (?) Rehoboth Terrane to the 0.9 to 1.3 Ga old Namaqua-Natal belt (Fig.3.1). The Rehoboth Terrane is bordered to the east by the Kheis-Magondi belt (1.7 to 2.0 Ga) and then to the Kaapvaal craton. The assembly of these geological units began at about 2.9 Ga with the collision of the two main Kaapvaal Craton building blocks (Schmitz et al., 2004). The Kheis-Magondi belt accreted along its western border between 1.93 and 1.75 Ga (Tinker et al., 2004), followed by the collision of the Rehoboth Terrane (Jacobs et al., 2008). The Rehoboth Terrane is a mixed age province with a nucleus that is possibly Archean (e.g. Hoal et al., 1995) and with products of major magmatic events from the time between 1.7 and 2.1 Ga and again from 0.9 and 1.3 Ga, the time of the Namaquan orogeny between (taken from summaries by Janney et al. (2010) and Cornell et al. (2011)). The latter authors make a case where the Rehoboth Terrane had an early common history with the Kaapvaal Craton, was separated and reunited at around 1.2 Ga. Magnetotelluric measurements

along a SE-NW profile of southern Africa show that the present day lithosphere underneath the Rehoboth Terrane is significantly thinner than underneath the Kaapvaal Craton (Muller et al., 2009) in agreement with the latest geothermobarometric evaluation in combination with other geophysical constraints by Mather et al. (2011). Maximum depth of the eastern Kimberley block is believed to be approximately 220-250 km, compared to approximately 180 km of the Rehoboth Terrane (Muller et al., 2009). These results also support earlier work by Bell et al. (2003) which suggested a cratonic thermal regime and similar lithospheric thickness across the Proterozoic and Archean southern Africa into the Mesozoic. Thermal erosion then destroyed the lower part of the Rehoboth lithosphere and local thermal disturbances reached to shallower depths in Namibia than underneath the Kaapvaal craton.

The Gibeon Kimberlite field stretches 70 km from East to West and 110 km from North to South (Kurszlaukis et al., 1998). It consists of more than 75 non-diamondiferous kimberlite pipes and carbonatite diatremes. They intruded into sediments of the Kalahari, Karoo and Nama groups which cover the basement. Kimberlite volcanism occurred at around 71.5 Ma (Davies et al., 2001) and was possibly triggered by the drift of the African continent over the Vema plume (Spriggs, 1988). To the present knowledge, the basement is made up of 1.6 – 1.8 Ga proterozoic metamorphic rocks (Hartnady and LeRoex, 1985).

Previous work on the localities Louwrensia, Hanaus, Gibeon Townlands and Anis Kubub by Mitchell (1984), Franz et al. (1996a), Franz et al. (1996b) and Boyd et al. (2004) established the thermal structure underneath the Gibeon Province at the time of kimberlite eruption [Fig. 3.2 modified from Bell et al. (2003)]. This figure shows that the conductive geothermal gradients beneath the Gibeon Province and the Kaapvaal craton coincide, that it stops at shallower depth in Gibeon and that there is a distinct departure of high temperature peridotites in both mantle areas from the main array. This occurs at shallower depth in Gibeon than on the Kaapvaal craton. Franz et al. (1996a), Franz et al. (1996b), Mitchell (1984) and Boyd et al. (2004) all distinguished granular and deformed peridotites. Franz et al. (1996a) and Franz et al. (1996b) distinguished coarse equant peridotites which mostly plot on the conductive geotherm, highly deformed mosaic-porphroclastic types which mainly belong to the high temperature peridotites and transitional porphroclastic types. Hoal et al. (1995), Franz et al. (1996a), Franz et al. (1996b) and Boyd et al. (2004) established the orthopyroxene rich nature of a portion of the Gibeon peridotites which is a common feature of Kaapvaal peridotites. In consequence, Hoal et

al. (1995) and Franz et al. (1996b) advocated the idea of an Archean lithospheric component within the Gibeon subcontinental lithosphere and the latter suggested that this may be rifted material from underneath the Kaapvaal craton. Such an idea is not supported by the Re depletion ages from 20 peridotites which range from 0.5 to 2.1 Ga (Hoal et al., 1995; Pearson et al., 2004).

Fig 3.1: The ca. 75 Ma old Gibeon kimberlite field within the framework of major crustal units of Southern Africa (after Hoal et al., 1995; Boyd et al., 2004).

### 3.4. Materials and Methods

We wanted to unravel the history of the Gibeon subcontinental mantle in more detail and carried out a comprehensive study of major and trace elements and isotope ratios on minerals from variously altered xenoliths from Hanaus and from Gibeon Townlands. They were available to us from own sampling and partly from the collection of Franz et al. (1996b).

Nineteen samples from more than 40 garnet peridotites were selected according to the variation of their clinopyroxene and garnet modal amounts with the aim to obtain the largest possible range in  $^{147}\text{Sm}/^{144}\text{Nd}$  and  $^{176}\text{Lu}/^{177}\text{Hf}$  ratios. All samples are variously altered, but

clinopyroxene and garnet were preserved in all of them and fresh olivine and orthopyroxene could be found in eleven xenoliths. Alteration varied from pervasive with extreme samples where all olivine and orthopyroxene were replaced by  $\text{SiO}_2$  and in others by unidentified sheet silicates and carbonates to alteration along cracks and grain boundaries by the same minerals. Structural types were difficult to establish but it could be seen that some of the samples belonged to the coarse granular and others to porphyroclastic types.

The xenolith sizes range from a few centimeters up to 10 cm. Five samples contained only very small amounts of clinopyroxene (KGG 91-20c, KGG 91-37, KGG 91-46, KHA 91-93, SKGGIVc); no clinopyroxene was found in one sample (SKGGIVb) and no garnet in another (SKGGIVd). Samples were prepared for major and trace element analysis either as polished thick sections (150  $\mu\text{m}$ ), or as mineral separates which were mounted in epoxy and polished.

Clean garnet and clinopyroxene separates were prepared for isotope analysis. In 14 samples, clinopyroxenes were surrounded by a thin rim (10 – 20  $\mu\text{m}$ ) of newly grown, sieve textured clinopyroxene (Table 3.1), probably as a result of reaction with the host kimberlite during ascent [already observed by Franz et al. (1996a)]. Great care was taken to avoid these portions during mineral separation. We achieved this by crushing the bulk samples with a SelFrag® fragmentation system using voltages of 90 - 120 kV and a built in sieve of 1 mm mesh size. In the SelFrag®, minerals are liberated along grain boundaries and fractures. Fresh, solid mineral pieces with grain sizes larger than 1 mm are retained by the sieve. Smaller pieces and the major proportion of the sieve textured clinopyroxene rims fell through the sieve. Only very minor amounts of sieve textured clinopyroxene still adhered to the large pieces which were removed by handpicking after the following procedure: The retained sample portion was dried and light and heavy fractions were separated using bromoform (density c. 2.9  $\text{g}/\text{cm}^3$ ). The heavy mineral fraction contained mostly only clinopyroxene and garnet which were quantitatively separated using a Frantz® magnetic separator. Modal proportions of clinopyroxene and garnet were determined by weighing the two fractions and cpx/grt ratios of the bulk rock were calculated. The material left from the SelFrag® sieving and the various separation steps was combined and weighed together. These portions approximate the (former) olivine + orthopyroxene modal contents. The results are given in Table 3.1. The overall error of the modal contents determined this way is taken to be about 10% relative. Modal mineral contents of four samples used in this study have been determined previously by Franz et al. (1996b) by pointcounting of thin sections.

In comparison to our present results and those of Boyd et al. (2004) on samples from Louwrensia, the garnet and cpx abundances seem to be overestimated.

Table 3.1: Modal contents, geothermobarometrical data and Lu-Hf and Sm-Nd isotope characteristics of the analyzed samples.

### **3.4.1. Major element analysis**

Major elements were determined in olivine, orthopyroxene, clinopyroxene and garnet with a Jeol JXA 8900RL Superprobe with five spectrometers in WDS mode with a beam size of 3  $\mu\text{m}$ , an acceleration voltage of 15 KV and a probe current of 20 nA. For each sample and each mineral, three grains were analysed, with three analyses from core to rim to test for homogeneity. Peak measuring times varied between 20 to 30 s, background measuring times were 10 to 30 s. Standards were a mix of natural minerals and pure oxides and metals. CITZAF© algorithm by John T. Armstrong was used for matrix correction.

### **3.4.2. Trace element analysis**

Trace elements were analysed by Laser Ablation Inductively Coupled Plasma Mass Spectrometry (LA-ICPMS) using a New Wave Research® UP213 ultraviolet Nd–YAG laser coupled with a Thermo-Finnigan® Element 2 at the Goethe University of Frankfurt.

Only unaltered and clear grains were considered for trace element analyses. For each sample, three grains of clinopyroxene and garnet were analysed with three laserspots from core to rim.

Analyses were performed with a spot size of 40  $\mu\text{m}$ , an energy density of c. 2  $\text{Jcm}^{-1}$  and a frequency of 10 Hz. We used as external standard a Nist 612 glass and CaO from microprobe analyses as an internal standard. Reference values for Nist 612 were taken from Pearce et al. (1997). The data were processed with the Gemoc GLITTER© software. USGS standard Bir-1G was always measured several times during an analytical session as secondary standard to monitor the machine performance and estimate the analytical precision and accuracy of the method. The obtained accuracy and precision for all analysed elements lie in the range of 5 to 10 %.

### **3.4.3. Isotope analysis**

Based on the relative amounts of clinopyroxene and garnet and their trace element abundances and the actual size, twelve samples appeared suitable for isotope analysis.

The garnets and clinopyroxenes were carefully handpicked under the binocular to avoid altered grains and the little left-over sieved-textured clinopyroxenes removed. They were

subsequently leached for 10 min in 2 M HCl which does not fractionate Hafnium or Neodymium isotopes as demonstrated by previous studies with 6 M HCl (DeWolf et al., 1996; Wittig et al., 2007). After rinsing with Milli-Q® H<sub>2</sub>O, samples were re-examined and then cleaned with Milli-Q® H<sub>2</sub>O in an ultrasonic bath for at least 1 hour. Each sample was weighed in and spiked with a <sup>176</sup>Lu-<sup>180</sup>Hf and <sup>149</sup>Sm-<sup>150</sup>Nd spike. Chemical separation of the desired elements was performed in three sessions ('batch') with 8 to 12 samples per session, each including one column for a blank and one for standard BCR-1.

One of three sample batches (see Table 3.1 'batch c') was dissolved in 5 mL 3:1 HF (24 M): HNO<sub>3</sub> (15 M) solution in closed Savillex® teflon beakers at 120°C for 24 hours. Before fuming off, 150 µL of 11.6 M perchloric acid was added in order to prevent the formation of fluorides. After evaporation to dryness, the sample cake was re-dissolved in 6 M HCl and placed with the closed lid overnight on the hotplate at 120°C.

Two of the three samples batches (see Table 3.1 'batch a and b') were dissolved by using a 3 mL 2:1 HF (24 M) : HNO<sub>3</sub> (15 M) acid mixture in closed Savillex® teflon beakers for three days on a hot plate at 120°C. Samples were ultrasonicated for 10 minutes in between. After fuming off the acid mixture, 6 M HCl and 6 M HNO<sub>3</sub> was alternatively added, heated overnight (120°C) and then fumed off for cracking down fluorides and achieving full dissolution.

Samples were dried down and taken up in 3 M HCl in which 0.1 M ascorbic acid was added. Ascorbic acid is needed to reduce Fe<sup>3+</sup> to Fe<sup>2+</sup>, as Fe<sup>3+</sup> may block the resin in the column (Muenker et al., 2001). Before loading the columns, each sample was centrifuged in order to remove any possible left over inclusions.

For the separation of Lu and Hf we followed the procedures of Muenker et al. (2001), using Eichrom® Ln.spec resin. The procedures of Muenker et al. (2001), were slightly modified by omitting the zirconium washing step and by using 2 M HF instead of 6 M HCl with 0.2 M HF for collecting Hf. Washing out the zirconium would result in a partial loss of Hf, which is not desirable considering the very low amounts of Hf down to 3 ng.

Following the procedures of Pin and Zalduegui (1997), light rare earth elements (LREE) were separated from the dissolved sample using Biorad 50Wx8 resin, while the separation of Sm and Nd were performed in Ln.Spec resin, using the same columns and digestion batch that were used for the Lu and Hf separation.

Because of the small amounts of samples, column sizes were reduced from conventional sizes to 1 mL resin volume for Ln.Spec columns and 1.5 mL in case of Biorad 50Wx8 columns.

Samples were measured using a Thermo-Finnigan® Neptune MC-ICPMS at the Goethe University Frankfurt with Ni x cones following the method described in Schmidt et al. (2008). In case of Lu and Hf isotope measurements a CETAC Aridus™ nebulization system (ca. 70 µL/min) was used to enhance sensitivity (e.g., Hf, 500-800 Vppm<sup>-1</sup>). A conventional glass spray chamber was used as sample introduction system for Sm and Nd. Procedural blanks were generally below 25 pg for Hf, below 10 pg for Lu, below 35 pg for Nd, and around 15 pg for Sm. Mass bias was corrected using of 0.7325 for the <sup>179</sup>Hf/<sup>177</sup>Hf and 0.7219 for <sup>143</sup>Nd/<sup>144</sup>Nd (Blichert-Toft et al., 1997). The mass bias for Yb was monitored with <sup>173</sup>Yb/<sup>171</sup>Yb = 1.1248 and used for interference correction of <sup>176</sup>Lu and <sup>176</sup>Yb on mass 176. Blank correction was performed for samples that contained very low amounts of Hf.

JMC 475, Merck and Ames standards were measured during the analytical sessions to assure high quality isotope measurements of Hf and Nd isotopes. The comparison with published reference values (Blichert-Toft et al., 1997; Caro et al., 2006) shows that this was achieved since we obtained isotope ratios of  $0.282149 \pm 0.000016$  for <sup>176</sup>Hf/<sup>177</sup>Hf and  $0.51173 \pm 0.000021$  for <sup>143</sup>Nd/<sup>144</sup>Nd (Merck) and  $0.51194 \pm 0.000011$  for <sup>143</sup>Nd/<sup>144</sup>Nd (Ames).

Measurements of the standard BCR-1 yielded isotope ratios of  $0.282865 \pm 0.000017$  for <sup>176</sup>Hf/<sup>177</sup>Hf and  $0.512627 \pm 0.000021$  for <sup>143</sup>Nd/<sup>144</sup>Nd. The measured ratios are in a good agreement with published data for Hf (see compilation Chu et al. (2002)) and Nd (see compilation Yang et al. (2010)). The data were processed using in-house Excel® spreadsheets. Age calculations, following isotope ratio calculations were performed using Isoplot 3.7 (Ludwig, 2008).

For single mineral analyses, errors for isotope ratios are based on an error propagation including the uncertainty of the spike calibration and the deviation from the reference value of the corresponding standard. For <sup>176</sup>Lu/<sup>177</sup>Hf, errors are in average around 0.8 % (1 sigma) and for <sup>176</sup>Hf/<sup>177</sup>Hf around 0.003 % (1 sigma). <sup>147</sup>Sm/<sup>144</sup>Nd ratios have an average error of around 0.2 % (1 sigma) and around 0.002 % for <sup>143</sup>Nd/<sup>144</sup>Nd (1 sigma).

For whole rock analyses, the error increases up to several percent for <sup>176</sup>Lu/<sup>177</sup>Hf and <sup>147</sup>Sm/<sup>144</sup>Nd and for <sup>176</sup>Hf/<sup>177</sup>Hf and <sup>143</sup>Nd/<sup>144</sup>Nd up to 0.028 % 0.0027 % (1 sigma) respectively,

depending on the isotopic characteristics and modal abundance of clinopyroxene and garnet of the individual sample.

### **3.5. Results**

#### **3.5.1. Major elements**

Our new mineral data from Hanaus and Gibeon Townlands (representative analyses selected for thermobarometry are given in Table A3.1) lie within the compositional spread of previous work as summarized by Janney et al. (2010). This means e.g. that all garnets plot in a CaO-Cr<sub>2</sub>O<sub>3</sub> diagram in the lherzolite field. Our garnets have 2 to 6 wt% Cr<sub>2</sub>O<sub>3</sub> except for one which contains 9 wt % Cr<sub>2</sub>O<sub>3</sub>. Forsterite contents in olivine (fresh remnants in only 11 samples) range from 90 to 93 with a peak between 91 and 92. This is identical with the compositional range and peak as derived by Janney et al. (2010) for a much larger data set for the Gibeon field and other off-craton occurrences. It contrasts with a peak between 92 and 93 for the Kaapvaal craton which reflect a higher average degree of depletion there. It is important to note that those olivines coexisting with garnets with sigmoidal shaped REE patterns (see below) are Fo-richer and closer to olivines from the Kaapvaal craton. All minerals are generally unzoned except very near to the rims as described for a restricted number of samples by Franz et al. (1996b).

##### **3.5.1.1. Geothermobarometry**

Pressures and temperatures of equilibration were calculated with  $T_{\text{BKN}}$  and  $P_{\text{BKN}}$  of (Brey and Koehler, 1990) to be directly comparable with previous work, but the use of the thermobarometer versions recommended by Nimis and Grutter (2010) would not change the results to any significance. These are given in Table 3.1 and shown in Fig.3.2 (modified from Bell et al. (2003)) as blue (LREE depleted patterns in garnets) and red symbols (sigmoidal REE patterns –see below). They coincide with the PT-fields of coarse equant, porphyroblastic and highly deformed mosaic-porphyroclastic peridotites of the Gibeon kimberlite field. One sample

(KHA 91-29) yields 805°C at 21.6 kbar. All other samples plot either along a conductive geotherm or to higher temperatures at similar pressures.

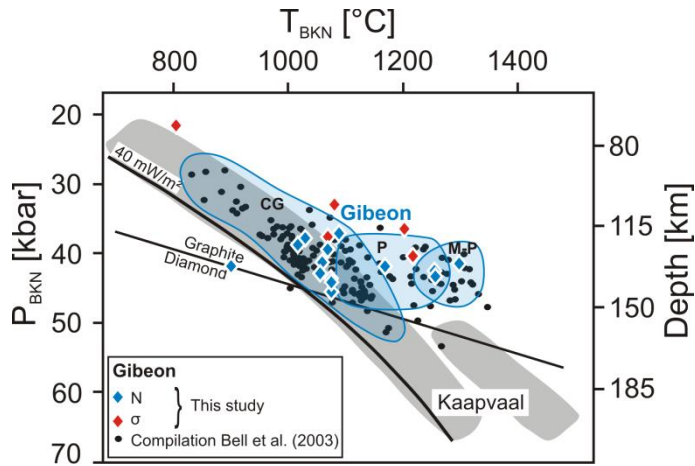

Fig.3.2: The thermal structure of the lithospheric mantle underneath Gibeon and the Kaapvaal craton (grey fields) after a compilation of mantle P/T conditions by Bell et al. (2003). Our new data for the Gibeon Townsland and Hanaus kimberlite pipes are shown as blue and red diamonds. Light blue shaded fields and abbreviations are textural classifications from Franz et al. (1996b): CG = Coarse Granular, P = Porphyroclastic, M-P = Mosaic-Porphyroclastic.

### 3.5.2. Trace elements

#### 3.5.2.1. REE and extended trace element patterns in garnets and clinopyroxenes

Averaged trace element contents of garnets and clinopyroxenes for the nineteen analyzed samples are given in Table A3.2 and shown as chondrite normalized REE patterns (McDonough and Sun, 1995) in Fig.3.3 a-b. Two peridotite types can be distinguished from the REE patterns: 13 samples with normal, flat HREE garnet patterns (described further on as N-type – Fig.3.3a) and 5 samples with sigmoidal garnet REE patterns (type ‘σ’ – Fig.3.3b).

Fig.3.3: Averaged REE patterns of garnets and clinopyroxenes from peridotites from the Hanaus and Gibeon Townsland kimberlite pipes normalized to C1 (McDonough and Sun, 1995). Coexisting garnets and clinopyroxenes for samples with LREE depleted garnet patterns (type N) are shown in A as blue lines and for samples with sigmoidal garnet patterns (type  $\sigma$ ) in B as reddish lines.

The clinopyroxenes have supplementary patterns to the garnets. Only sample SKGGIVa is different to all other samples with a sigmoidal garnet and a normal clinopyroxene REE pattern (Fig.3.3) which do not correspond to equilibrium partitioning (Fig.3.4).

The REE patterns of both N- and  $\sigma$ -type garnets and clinopyroxenes are composites of at least two components: i) The garnets of the N-peridotites have flat (HREE)<sub>N</sub> patterns and variable contents but the LREE of each sample are elevated relative to a smooth decrease to La as dictated by the ionic radii. ii) The  $\sigma$ -type peridotites have fractionated (HREE)<sub>N</sub> patterns and variable contents and the LREE and most MREE are elevated and bow-shaped compared to the HREE. Normalization of minerals to primitive chondrite only serves the purpose to visualize analytical results. Instead, we normalized in Fig. 3.5a and 3.5b the REE, Y, Sr and the LILE of garnets resp. clinopyroxenes to those from garnet peridotite 313-105 from, Vitim (Siberia; (Ionov et al., 2005)).

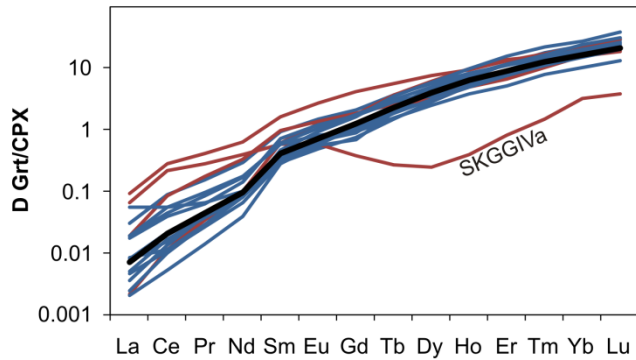

Fig.3.4: Garnet/clinopyroxene partition coefficients for N-peridotites (blue) and  $\sigma$ -peridotites (red) compared to the primitive peridotite from Vitim, Siberia (black line; (Ionov et al., 2005)). All samples are in inter mineral equilibrium except for sample SKGGIVa which is not considered any further.

This peridotite is very close to a primitive mantle composition and the garnet and clinopyroxene REE patterns correspond to those of an undepleted mantle (strictly speaking only to those at the P, T-conditions of this sample which are 21 kbar and 1034°C). The normalization of the Gibeon garnets and clinopyroxenes to those from Vitim show relative changes caused by depletion and reenrichment (Fig.3.5a,b). All HREE of our samples are lower than one; the blue band resp. the red band gives the range and a visual estimate of a smooth decrease according the ionic radii and the arrows visualize the degree of overabundance of the more incompatible elements.

Fig.3.5: A and B: Extended trace element patterns of garnets and clinopyroxenes normalized to Vitim 313-105 garnet and clinopyroxene (Ionov et al, 2005). This sample is taken as a measure for the primitive Earth. A coincidence at one would indicate no change; deviation of incompatible elements to lower values indicate partial melting and to higher values reenrichment. HREE are lower than one and the blue (N) and red ( $\sigma$ ) fields are estimates of the shape of the trace element patterns after partial melting. The blue and red arrows indicate subsequent enrichment. C: Calculated REE whole rock compositions based on the relative proportions of garnet and clinopyroxene and the combined modal amounts of olivine + orthopyroxene. PUM = Primitive upper mantle (McDonough and Sun, 1995). D: Non modal fractional melting curves (taken from Lazarov (unpublished results; PhD Thesis)) for the spinel (green) and the garnet stability field (red) in comparison to the calculated bulk rock compositions. These are indicated by the red and blue shaded areas.

### 3.5.2.2. Calculated REE bulk rock compositions

Another way to visualize depletion and enrichment effects is to calculate whole rock compositions from the modal amounts of the minerals and their composition and compare them

with the primitive mantle. Whole rock REE patterns were calculated based on the relative amounts of clinopyroxene and garnet and the amounts of olivine + orthopyroxene (see above under Materials and Methods and Table 3.1). Olivine and orthopyroxene were assumed to contain no REE.

### 3.5.2.3. Trace element partitioning between garnet and clinopyroxene

In the sample set from Hanaus and Gibeon Townlands we distinguish N-type peridotites with flat  $(\text{HREE})_{\text{N}}$  and  $\sigma$ -type peridotites with fractionated  $(\text{HREE})_{\text{N}}$ . Despite the very different trace element patterns the garnet-clinopyroxene element partitioning must fulfill inter-mineral equilibrium criteria at the high mantle temperatures, if there was no selective disturbance of a mineral shortly before eruption through the kimberlite. This means that partition coefficients must be the same for the same P, T conditions and major element composition and must show systematic shifts with differing pressure, temperature and compositional parameters. Most of our N samples stem from PT-conditions between 35 to 45 kbar and 1000 – 1100°C and half of the  $\sigma$  types from similar pressures, but temperatures between 1200 – 1250°C. Fig.3.4 shows that the REE partitioning between garnet and clinopyroxene is very similar for the HREE for all samples but that the LREE partition coefficients are higher for the  $\sigma$  samples and lower for the N samples. Sample SKGGIVa is very different to all other samples and garnet and clinopyroxene apparently are in disequilibrium. Also shown in Fig.3.4 is the REE partitioning for the Vitim peridotite 313-105 which overlaps with the HREE partitioning and the lower range of the LREE. This sample equilibrated at 21 kbar and 1034°C. Its REE partitioning agrees with the experimental results of (Green et al., 2000) at similar P,T-conditions. A whole range of further trace elements were analyzed in this sample (Ionov et al., 2005) which enables us to test more elements for equilibrium (Fig.3.6). We normalized the garnet-clinopyroxene partition coefficients of Nb, Ta, Sr, Zr, Hf, Y and the REE from our samples to those of Vitim 313-105. The normalized partition coefficients of the HREE and Y plot at around one which is consistent with a temperature independent partitioning behaviour. The middle and light REE and Sr split into a fan whereby  $D^{\text{grt/cpx}}_{\text{sample}}/D^{\text{grt/cpx}}_{\text{Vitim}}$  for La are below 1 for the lower temperature xenoliths and up to 10x for the higher temperature xenoliths. Zr and Hf show a similar range of temperature dependency whereas Nb and Ta range between about 2 and 15. All but one of the

investigated samples from Hanaus and Gibeon Townlands appear to be in internal mineral equilibria - an important prerequisite for the study of the Sm-Nd and Lu-Hf isotope systems of garnet and clinopyroxene.

Fig.3.6: Garnet/clinopyroxene partition coefficients of our samples normalized to the partition coefficients of a primitive garnet peridotite 313-105 from Vitim, Siberia (Ionov et al., 2005). This sample was equilibrated at 2.1 GPa and 1034°C. Pressures of our samples are higher on average by about 2 GPa whereas temperatures are very similar for most of the samples. The partition coefficients plot at around one for the HREE whereas the more incompatible elements increasingly deviate to greater values for the higher temperature peridotites. Nb and Ta seem to be systematically offset.

### 3.5.3. Isotopic composition

#### 3.5.3.1. Lutetium-Hafnium

The results for Lu-Hf isotope system of all samples are given in Table 3.1 and shown in Fig. 3.7a for the N samples. Coexisting garnets and clinopyroxenes are connected by tie-lines whose slopes yield ages ranging from 268 to 746 Ma. These ages are from samples with equilibration temperatures of around 1050°C, a temperature which may be below the closure temperature of the Lu-Hf system. One sample with an equilibration temperature of around 1300°C and which is in apparent mineral equilibrium gives a tie-line age of 1791 Ma (HAN 93-20). In the three samples with sigmoidal REE patterns the modal amount of clinopyroxene was too low (< 0.1%) and the sample size too small to obtain sufficient clean clinopyroxene separates and isotopes

could be measured only in garnet. One sample (SKGGIVa) contained sufficient clinopyroxene but is out of internal mineral equilibrium (see above) and is not considered any further.

Fig.3.7: A and B: Lu-Hf and Sm-Nd tie line ages for clinopyroxene (green diamonds) and garnet (red diamond) pairs. The ages range from 746 to 268 Ma for the Lu-Hf system (except for one very much ‘older’ sample) and are similar to the kimberlite eruption age (except one) for the Sm-Nd system. Almost all samples stem from temperatures between 1050 and 1100°C. This temperature range seems to be below the closure temperature for Lu-Hf and above for Sm-Nd, i.e. this isotope system was in inter mineral equilibrium until the time of eruption.

Based on the relative proportions of garnet and clinopyroxene, whole rock  $^{176}\text{Lu}/^{177}\text{Hf}$  and  $^{176}\text{Hf}/^{177}\text{Hf}$  ratios were calculated for group N samples and plotted in an isochron diagram (Fig.3.8a). The error bars are a combination of the errors from the isotope and trace element measurements and the determination of the relative modal amounts of clinopyroxene and garnet. Four samples yield an age of  $810 \pm 51$  Ma with an initial of 0.282365 ( $\epsilon\text{Hf}_{\text{CHUR}} = + 3.3$ ) and MWSD = 2.8. This is a minimum age because the possible effect of orthopyroxene. Lu and Hf

contents in orthopyroxenes are low and their ratio is about  $\frac{1}{4}$  of that of coexisting garnet (judging from our previous work on peridotites from the Finsch diamond mine (Lazarov, Unpublished results; PhD Thesis).  $^{176}\text{Lu}/^{177}\text{Hf}$  is therefore somewhat lower than that of the calculated bulk rocks. The 'real bulk'  $^{176}\text{Lu}/^{177}\text{Hf}$  would be lower maximal by 5 % and  $^{176}\text{Hf}/^{177}\text{Hf}$  by 0.5%. This would add 38 Ma to the above number.

The three  $\sigma$  garnets yield an age of 1852 Ma  $\pm$  100 Ma and an initial of 0.28243 ( $\epsilon\text{Hf}_{\text{CHUR}} = +29.4$ ) and MWSD = 3.1. The isotopic composition of clinopyroxene could not be measured and we estimate from its trace element composition and its abundance of less than 0.01 % that it will reduce the age by about 2 Ma at the most. The neglected orthopyroxene would add a maximum of 86 Ma to the age.

#### 3.5.3.2. Samarium-Neodymium

The results for Sm-Nd of all samples are given in Table 3.1 and shown in Fig. 3.7b for the N samples. Coexisting garnets and clinopyroxenes are connected by tie-lines whose slopes yield ages from 18 to 110 Ma (one exception lies at 304 Ma) roughly around the eruption age of about 71.5 (Davies et al., 2001) Ma assumed for the kimberlite field. The Sm-Nd system was in inter mineral isotopic equilibrium up to the time of eruption in most samples. Temperatures of around 1050°C appear to be above the closure temperature for the Sm-Nd isotopic system in peridotites. Since only garnets could be measured from the  $\sigma$  samples, their isotope ratios are representative for the bulk rock. The results for the garnets are shown in Fig. 3.8b together with the whole rock isotopic compositions of the N samples. No correlation is discernible in the whole data set. The peridotites are a complex product of partial melting and metasomatic overprint which affects the LREE most strongly. The Sm and Nd isotope ratios for the N-type peridotites are a mixed signal which cannot be resolved. The three  $\sigma$  garnets yield an age of 458  $\pm$  32 Ma which may be a realistic age because metasomatism probably did overprint Sm and Nd completely because of the low contents after high degrees of partial melting (see below).

Fig.3.8: A: Calculated whole rock isochrons for the Lu-Hf system. This system yields an isochron age of 810 Ma for the N-peridotites and 1852 Ma for the  $\sigma$ -peridotites. Both isochrons are interpreted as enrichment ages because Hafnium was reintroduced into these mantle portions (compare Fig.3.5). B: The Sm-Nd isotope system yields a scatter for the N-peridotites because of (multiple?) re-enrichment processes which affected mostly the LREE. The correlation of the  $\sigma$ -peridotites may represent a further enrichment at around 458 Ma.

### 3.6. Discussion

We have established the Hanaus and Gibeon Townlands xenoliths as a diverse suite of depleted and re-enriched peridotites which can be divided into two groups  $\sigma$  and N by their garnet REE patterns. A twofold division is also expressed in their modal mineral abundances (type  $\sigma$  have lower clinopyroxene contents), their major element composition (e.g. higher forsterite on average in  $\sigma$ -olivines) and in the Lu-Hf isotope systematics (type  $\sigma$  give a Lu-Hf age of 1852 Ma with  $\epsilon_{\text{Hf}}^{\text{CHUR}} = +29.4$  and type N an age of 810 Ma with  $\epsilon_{\text{Hf}}^{\text{CHUR}} = +3.3$ ). These differences are expressions of different melting regimes and of partial melting and re-enrichment at different times.

Depletion and enrichment compared to a primitive Earth's mantle is visualized in Fig.3.5, where we normalize the HREE and the more incompatible trace elements of garnets and clinopyroxenes to those of the primitive Vitim sample 313-305. The blue and red bands indicate the hypothetical range of the more incompatible trace elements for the N- resp.  $\sigma$ -type peridotites as dictated for the HREE abundances for partial melting. The measured trace

elements are substantially higher and the red and blue arrows indicate the respective enrichments. This metasomatic ‘overabundance’ is seemingly higher in the  $\sigma$  than in the N peridotites. However, modal abundances of garnet and clinopyroxene are lower in  $\sigma$  than in N peridotites and the same amount of metasomatic agent affects the former much more than the latter. Nevertheless, the Sm and Nd contents of the  $\sigma$  minerals were very low after depletion and their present abundances must stem mostly from the metasomatic agent. The Sm-Nd system therefore provides age information on the timing of metasomatism of the  $\sigma$ -peridotites (Fig.3.5a). The Sm-Nd contents of the N samples are a mix of residual and reintroduced components and their isotope systematics give a mixed signal. It can also be seen in this figure that Hf and Zr are elevated compared to a hypothetical residual peridotite and that they are reintroduced as well. It follows that the Lu-Hf Isochrons found for the N- and  $\sigma$ -type peridotites (Fig.3.8) also date enrichment events.

Measures of depletion and indicators of the melting regime in residual peridotites are HREE abundances, HREE fractionation and Cr-Al<sub>2</sub>O<sub>3</sub> and Y-Al<sub>2</sub>O<sub>3</sub> whole rock relationships. In the following, we use the HREE as the unmodified composition of the residual peridotites since the time of last partial melting. Their contents and relative abundances allow us to estimate degrees of partial melting and judge whether partial melting has occurred in either the spinel or garnet peridotite field or both. Fig. 3.5c shows the calculated REE patterns of the samples from Gibeon, for which modal data are given in Table 3.1 and Fig.3.5d shows the results for non-modal fractional melting calculations in the spinel and garnet stability field. The qualitative comparison of the range of M- to HREE abundances in the N peridotites indicates 15 to 20 % of partial melting in the spinel peridotite field. The  $\sigma$ -type peridotites appear to be the products of 15 – 25 % partial melting as judged from the HREE abundances. This is combined with mild to strong HREE fractionation. These two features together indicate partial melting in the spinel and garnet stability field. Our interpretation is that these peridotites suffered successive melting first at low pressures, followed by subduction and subsequent melting in the garnet stability field. Boyd et al. (2004) had used the Y-Al<sub>2</sub>O<sub>3</sub> relationship to suggest that partial melting occurred at pressures less than 3 GPa for the xenolith suite from the neighbouring Louwrensia kimberlite pipe.

### *The timing of enrichment*

The Sm-Nd isotope system a priori has the highest potential to date enrichment processes in the mantle. These two light rare earth elements are readily affected by the fractionated, LREE rich mantle metasomatic agents while the HREE and Hf will see the impact only at high to very high degrees of overprint. A clear enrichment age signal can be expected for Sm-Nd when the original peridotite was strongly depleted and when there is only one metasomatic overprint. This could be the case for the  $\sigma$  peridotites for which we obtained about 460 Ga as a possible enrichment age. The Lu-Hf system should then yield the same age. Yet we obtained  $\sim 1.9$  Ga as an enrichment age. This difference could be reconciled if a first enrichment at 1.9 Ga was caused by an agent with a relatively flat REE pattern like a silicate melt and the second by a silicocarbonatitic or kimberlitic melt which did not affect Hf anymore. The age of 1.9 Ga lies in the middle of the 1.7 – 2.1 Ga crust forming period known from the Rehoboth province (e.g. Cornell et al. (2011)) and is older than the presently presumed basement age of 1.6 – 1.8 Ga (Hartnady and LeRoex, 1985). A 460 Ma enrichment may be connected with the accretion of the Damara orogen. The N-type peridotites gave an enrichment age of 810 Ma which may herald the final stages of the Namaqua orogeny. Both Lu-Hf isochrones have high, positive  $\epsilon_{\text{Hf}}$  initials which shows that Hf was reintroduced into an already depleted mantle. The  $\epsilon_{\text{Hf}}$  is substantially higher for the  $\sigma$ -type (+ 30) than for the N-type peridotites (+ 3). These differences further demonstrate, that the former are residues from higher degrees of partial melting (which partly occurred in the garnet stability field) than the N-type peridotites, that first melting of the  $\sigma$ -peridotites occurred before and for the N-peridotites later than 1.9 Ga.

### *Timing of partial melting*

We could not find direct evidence from both isotopic systems for the timing of the first melting event(s) of these different mantle portions. The high  $\epsilon_{\text{Hf}}$  of the  $\sigma$ -peridotites requires that depletion occurred either shortly before 1.9 Ga for high Lu/Hf in the residue or earlier for low Lu/Hf ratios. Model calculations show that melting should have occurred at around 2.3 Ga for 20 % non-modal batch melting in the spinel stability field and at around 2.8 Ga for 10 %. Twenty percent non-modal fractional melting reduces the time span between partial melting and

reenrichment to less than 100 Ma for melting either in the spinel or garnet stability field. This range is extended to 2.5 Ga for 10 % melting in the spinel field but remains short for melting in the garnet field. The low positive  $\epsilon_{\text{Hf}}$  for the N-peridotites requires that partial melting occurred only several hundred million years before 810 Ga.

The Re-Os isotopic system has the greatest potential to date partial melting events in a peridotitic mantle. However, statistically significant isochrons have not been reported so far, because the isotopic system, and especially Re, can be altered subsequent to an event in various ways (see summary article by Rudnick and Walker (2009)). Model ages (Re model ages  $T_{\text{MA}}$  and Re depletion ages  $T_{\text{RD}}$ ) as intersections with a model mantle evolution curve are in use instead, whereby  $T_{\text{RD}}$  comes close or corresponds to the true age of melt extraction for very high degrees of partial melting (Walker et al., 1989). If an isochron exists, the  $T_{\text{MA}}$ 's of each point along the isochron is identical with the isochron age, provided that a primitive mantle is melted and that the chosen Re-Os mantle evolution line is correct. Rhenium-Os isotope data are reported by Pearson et al. (2004) for 21 peridotites from Louwrensia in the Gibeon province and the platinum group element (PGE) contents in six of them. The textural types, the occurrence of samples with normal and enhanced modal orthopyroxene contents and the range of calculated pressures and temperatures are very similar for xenoliths from the three localities Louwrensia, Hanaus and Gibeon Townlands (compare Boyd et al. (2004) and Franz et al. (1996b)). The Re-Os data from Louwrensia may therefore be representative for the Gibeon province. They are reproduced in Fig. 3.9 together with the six PGE patterns analyzed from there. Oldest Re depletion ages from Louwrensia (calculated for a chondritic Earth model; (Walker et al., 1989)) are 2.1 Ga, 2.0, 1.98 and 1.94 Ga. These ages increase by about 200 Ma for the Primitive Upper Mantle (PUM) model of Meisel et al. (2001). Model ages ( $T_{\text{MA}}$ ) calculated with PUM reach 2.65 Ga (Fig. 9, ignoring the 2.83 Ga from a Re-enriched sample). The PGE pattern of the 2.65 Ga and this age approaches the real age of partial melting. Discarding the two data points with the kinky PGE patterns on the left side of the diagram, six points form a limiting line with a slope corresponding to an age of 2.9 Ga. Four of these data points are highly colinear and give an age of  $2885 \pm 51$  Ma, with  $^{187}\text{Os}/^{188}\text{Os}_{\text{initial}}$  of  $0.10984 \pm 0.00014$  and a MWSD = 0.16. The initial is slightly higher than the value for a chondritic Earth model ( $\gamma_{\text{Os}} = 2.44$ ) and less so for the PUM model of Meisel et al. (2001) ( $\gamma_{\text{Os}} = 1.21$ ) and  $T_{\text{MA}}$ 's slightly decrease from 2.67 to 2.49 Ga along this line. These results from the model calculations do not prove the reality of this isochron. PGE's

are measured only from one of the samples (see above). A proof for the reality of the isochron would be, if the other samples also showed that Re was not reintroduced. In that case partial melting occurred already in the Archean and would overlap with partial melting of the Kaapvaal subcratonic mantle.

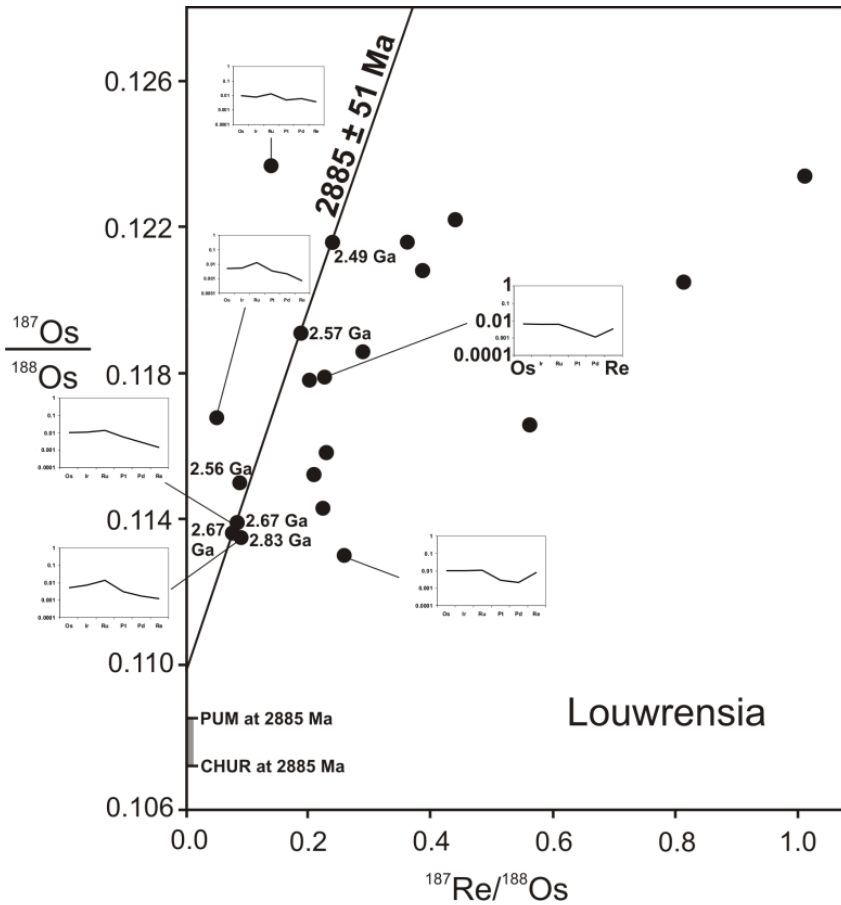

Fig.3.9: A tentative reinterpretation of the Re-Os data by Pearson et al. (2004) from Louwrensia. Oldest  $T_{MA}$  ages (PUM model) of 2.67 Ga indicate late Archean melting. A line through samples with a restricted range of Re model ages between 2.67 and 2.49 Ga gives an age of 2885 Ma. This isochron may be real because its initial is close to that of a primitive mantle at that time. It may record partial melting in the Archean.

Melting in the Archean within the circum cratonic mantle is supported by ten  $T_{RD}$  ages between 2.4 and 2.6 Ga (chondritic Earth model) resp. 2.6 to 2.8 Ga (PUM model) in other off-craton areas in southern Africa (Janney et al., 2010). Further support for an Archean component in the Rehoboth province comes from recent work by Cornell et al. (2011) who report zircon

ages between 2.7 and 2.9 Ga from trondhjemitic cobbles in Dwyka tillites of the Rietfontein area, which they consider as samples of the directly underlying crust. Furthermore, Van Schijndel et al. (2011) found detrital zircons in the Rehoboth Basement Inlier with ages between 2.7 and 2.9 Ga. We found 4 zircon grains with ages between 2.7 and 2.9 Ga (see Chapter 4) in a zircon separate from the Louwrensia kimberlite pipe.

### 3.7. Conclusions

Our new geochemical data, the age constraints from the Sm-Nd and Lu-Hf systems, the reinterpretation of the Re-Os system, age constraints from crustal rocks and the results from geothermobarometry and magnetotellurics (Muller et al., 2009) lead us to depict the following sequence of events in the assembly of the geological units of southern Africa:

The major part of the Kaapvaal craton assembled at about 2.9 Ga ago by the collision of East block and the West block along the Colesberg lineament (Schmitz et al., 2004). Oldest recorded  $T_{RD}$  and crustal ages from the W-block are around 3.1 Ga (Carlson and Moore, 2004; Schmitz et al., 2004) and from the E-block 3.2 resp. 3.6 Ga (Kroner et al., 1996; Carlson and Moore, 2004).  $T_{RD}$  ages have a maximum at around 2.88 Ga for both the E- and the W-block. Lu-Hf-ages for mantle samples from Finsch on the W-block give about 2.6 Ga. (Lazarov et al., 2009). The youngest major Archean crustal event on the Kaapvaal craton is represented by the 2.7 Ga old Ventersdoorp lavas.

At the time of collision of the Kaapvaal E- and W-blocks at 2.9 Ga the first mantle segments of the lithospheric mantle of the Rehoboth Terrane were created by partial melting at relatively shallow levels in the spinel stability field. Segments of the Rehoboth crust (probably independent of the Kaapvaal craton) existed at that time and residual spinel peridotite was placed underneath this crust by subduction or a similar process to be transformed into garnet peridotite. These are parallels to the generation of the Kaapvaal mantle as envisaged by a number of authors (e.g. Pearson and Nowell, 2002). The principal difference is the lower degree of partial melting on average. Attachment of the Rehoboth Terrane occurred somewhere around 2 Ga which is about the time of re-enrichment at 1.9 Ga recorded in the  $\sigma$ -peridotites. Re-enrichment may have occurred in a mantle wedge setting, may simultaneously have triggered second stage partial melting and may have been ultimately responsible for magmatic activity in the overlying crust.

Ages of 1.7 to 2.1 Ga are reported in the overlying crust in the Aroab Subprovince and in granite boulders in the Dwyka tillites (Blignault et al., 1974; Hoal et al., 1995; Cornell et al., 2011).

The N-type peridotites originated as low pressure partial melting residues sometime in the middle to early Proterozoic and were subducted underneath the Rehoboth province in the course of the Namaquan orogenic cycle between 0.9 to 1.3 Ga. This mantle portion was reenriched at the end of this period at around 850 Ma years ago.

A common thermal history and lithosphere thickness was established across the block consisting of the Rehoboth province, the Kheis Magondi belt and the Kaapvaal craton until the Mesozoic (Bell et al., 2003) when first, the lower parts of Kaapvaal lithosphere between 170 and 200 km were thermally disturbed and partly eroded sometime around about 150 Ma and second, the part of the Rehoboth lithosphere below about 140 km was removed and the mantle section between 120 and 140 km thermally overprinted (Bell et al., 2003; Boyd et al., 2004; Janney et al., 2010; Mather et al., 2011). This happened in the realm and at the beginning of the break-up of Gondwana and the opening of the Atlantic.

### **3.8. Acknowledgements**

The authors thank M. Lazarov and A. Neumann for support in the laboratory. Help during preparation by J. Heliosch and M. Krebs is gratefully acknowledged. Many thanks to L. Franz for providing additional samples. We thank S. Aulbach for helpful discussions. This project was supported by the Deutsche Forschungsgemeinschaft, grant BR 1012/37-1.

## **Chapter 4:**

# **U-Th-Pb and Hf isotope systematics of zircons from carbonatite and kimberlite derived crustal xenoliths: implications for the crustal evolution of the Rehoboth Terrane**

### **4.1. Abstract**

Knowledge about the crustal basement age of the Rehoboth Terrane in Namibia is only sketchy because of an extensive cover of Nama Group sediments. Known ages are Proterozoic. For this study we separated zircons from six crustal xenoliths from carbonatite dykes close to Gross Brukkaros, from one xenolith from the Louwrensia kimberlite diatreme and also from the matrix of the Louwrensia kimberlite. We determined the U-Pb ages of the zircons and their Hf isotopes by laser ablation ICPMS (Element 2 resp. Neptune from Finnigan). The xenoliths are high grade gneissic rocks of sedimentary origin.

Individual xenoliths give individual age spectra with main peaks at around 650 Ma, 1100-1200 and 1900 Ma. These ages also appear in the kimberlite matrix sample. The youngest ages are around 500 to 600 Ma. The kimberlite matrix contained a few zircons with ages of 2.4 to 2.9 Ga.

The combined Hf and U-Pb isotope data of zircon point to a prolonged history of juvenile crust formation, recycling and mixing.

The first crust may have been generated in the Archean from a primitive mantle source around 2.7 to 2.9 Ga ago or from a depleted source about 3.38 Ga ago with subsequent recycling around 1.9 to 2 Ga.

Palaeoproterozoic to Neoarchean crust was recycled during the attachment of the Rehoboth Terrane to the Kaapvaal craton at around 2.0 to 1.8 Ga. This coincides with the time of mantle enrichment as determined by the Lu-Hf isotope system on garnet peridotites from the Gibeon kimberlite field (Luchs et al., submitted, Precambrian Research).

Juvenile Mesoproterozoic crust was generated at around 1.5 to 1.6 Ga from a depleted mantle source, which was constantly recycled until 1.1 Ga and shows crustal mixing trend around 1.3

Ga. Nearly 60% of all datapoints are lying within this age range and are interpreted to mark a subduction process beneath the Kalahari plate (Becker et al., 2006).

More juvenile crust was formed at the boundary to the Neoproterozoic at 0.8 to 1.1 Ga that was subsequently recycling during the Namaquan and Pan African Orogeny.

## 4.2. Introduction

The Rehoboth Terrane in Namibia has often been described as an enigmatic province within the geotectonic framework of southern Africa (Hartnady et al., 1985) because of its patchy record of diverse crustal ages from scarce outcrops looking out from underneath a widely spread cover of Nama group sediments (Fig. 3.1 and 4.1). Crustal basement rocks can mainly be found in the Rehoboth Basement inlier which is situated in the north of the terrane, on the southern edge of the Ghanzi Chobe Belt. On its western border to the Proterozoic Namaqua Natal belt, the non diamondiferous Gibeon Kimberlite Province is situated. Kimberlitic volcanism as a consequence of the drifting of the African continent over the Vema Hot spot (Spriggs, 1988) lifted up numerous mantle and crustal xenoliths to the surface. These xenoliths were subject for several geochemical studies (e.g. Hoal et al., 1995; Franz et al., 1996b; Franz et al., 1996a; Pearson et al., 2004).

Analyses of these peridotites revealed a complex depletion and enrichment history of the upper mantle beneath Gibeon. Rhenium depletion ages for mantle xenoliths range from less than 0.5 up to 2.2 Ga (e.g. Hoal et al., 1995; Pearson et al., 2004), whereas only the oldest ages have a geological significance as Rhenium depletion ages ( $T_{RD}$ ). These ages can only be considered as minimum ages. Our major, trace and isotope (Sm-Nd, Lu-Hf) analyses of garnets and clinopyroxenes from garnet peridotites together with results from Re-Os (Pearson et al. (2004) indicate that the mantle underlying the Gibeon province is mainly made up of two different components (Luchs et al., submitted). A highly depleted and reenriched component with sigmoidal garnet REE patterns is possibly the residue of a first partial melting event at around 2.9 Ga (from Re-Os (Pearson et al., 2004); own interpretation). It may have been reenriched at around 1.9 Ga (Luchs et al., submitted) by a process connected with the collision of the Rehoboth Terrane with the Kaapvaal craton. The second, less depleted component (depletion age unknown) has flat middle to heavy garnet REE patterns with LREE enrichment. The Lu-Hf

isotope systematics give an age of around 850 Ma (Luchs et al., submitted) which corresponds to the very late stage of the Namaqua Natal orogeny. This mantle portion is thought to be a subducted addition to the Rehoboth mantle during the Namaqua Natal orogeny. Eventually, both mantle proportions were affected by a late enrichment around 460 Ma (Luchs et al., submitted).

In addition, a few zircon grains separated from a garnet peridotite of Hanaus I from Gibeon yielded three age clusters at 627, 751 and 1013 Ma, which can be related to magmatic events within the Damara belt (0.6 & 0.7 Ga) and the Namaqua Orogeny (1.0 Ga) (Liati et al., 2004).

The few crustal ages that have been determined in older studies from the Rehoboth Terrane revealed Proterozoic ages around  $895 \pm 7$  Ma (K-Ar; (Rupprecht, unpublished results; PhD Thesis))  $1.7 \pm 0.010$  Ga (Nagel et al., 1996) and  $1.7 - 2.3$  Ga ( $^{207}\text{Pb}/^{206}\text{Pb}$  and Nd model ages; (Ziegler and Stoessel, 1991)), whereas the Rehoboth basement inlier (RBI) is marked by an intrusive episode of  $1210 \pm 7$  Ma and an episode of igneous activity from at least 1.23 to 1.09 Ga (Becker et al., 2006).

More recent studies by Cornell et al. (2011), Van Schijndel et al. (2011b) and Van Schijndel et al. (2011a) of zircon and baddeleyite grains extracted from mafic and granitic Dwyka tillite cobbles brought up new light into the development of the Rehoboth crust and extended the age range into the Archean with ages ranging up to 2.9 Ga for detrital zircons from the RBI (Van Schijndel et al., 2011a) and 2.9 Ga from granitic cobbles of Dwyka Tillites (Cornell et al., 2011). The age spectra of Van Schijndel et al. (2011a) additionally contains major peaks from 1.05 to 1.32 Ga and 1.9 to 2.2 Ga corresponding to the Namaquan orogeny and a major crust building phase for the Rehoboth Terrane respectively. Baddeleyite grains from mafic cobbles that were separated from Dwyka tillites of Van Schijndel et al. (2011b) were dated with U-Pb around 1.11 Ga.

In this study, we analyzed a new sample set of zircons that were derived as xenoliths in carbonatites and a kimberlite from the lower to the middle crust and one sample collected from the matrix of the Louwrensia kimberlite pipe in the Gibeon Kimberlite Field for U-Pb and Hf isotopic compositions. Our basic assumption was that the crustal xenoliths derived from the middle to lower crust could provide new information about the framework of the Gibeon crust. The zircon population in the gneisses would give the maximum possible age of the sedimentary precursor (= the youngest zircons) and the oldest ages of the hinterland from which the sediments were derived (= oldest zircons). Magmatic rocks give information of a magmatic event

in the crust and the detritus from a volcanic diatreme (zircons are from disintegrated crustal rocks) possibly a complete overview of the ages of the crust underneath the Gibeon province. We also tried to clarify the question of whether there is a connection between mantle and crustal processes and if there is an Archean component existent in the Rehoboth Terrane as proposed before in several former studies (e.g. Hoal et al., 1995; Cornell et al., 2011; Luchs et al., submitted).

### 4.3. Geological setting

On the western border to the Namaqua Natal belt, the Gibeon Kimberlite field forms part of the Rehoboth Terrane (see Fig.3.1), alternatively termed as the Namibia province or Maltahoehe province (Blignault et al., 1974; Tankard et al., 1982).

Fig.4.1: Location of the Gibeon Kimberlite field within the southern African framework (after Kurszlaukis et al. (1998)). Marked in red ellipses are the sample locations for samples used in this study. A broader overview is given in Fig.3.1.

After the consolidation of the Kaapvaal craton at around 2.9 Ga, the Kheis-Magondi belt accreted along its western and south-western border, followed by the collision of the Rehoboth Terrane on its western margin at 1.9 Ga. At the time of collision of both Kaapvaal blocks, the

mantle of the Rehoboth Terrane probably already experienced its first depletion (Luchs et al., submitted) and crust had already existed (Cornell et al., 2011; Van Schijndel et al., 2011a).

Cornell et al. (2011) proposed an alternative scenario in which the Rehoboth Terrane and the Kaapvaal craton were attached from the Archaean, later separated, followed by a collision during which the Kheis-Magondi belt was formed.

During the Proterozoic, several terranes collided with the Kaapvaal craton and the Rehoboth Terrane in the west and in the south, forming the Namaqua-Natal belt with addition and enrichment of mantle components into the Rehoboth mantle around 0.8 to 0.9 Ga. At a later stage, during the Pan African orogeny, the Damara, Gariep and Saldania Belt were created. There is a general decrease of crustal basement ages away from the Archaean Kaapvaal craton towards the Atlantic Ocean, with some exceptions in between such as the Richtersveld subprovince with ages ranging from 2.0 to 1.7 Ga. It remains unclear if it represents a part that remained unaffected by the Namaqua orogeny or if had already formed in the protoatlantic and then collided with the Namaqua-Natal mobile belt (Hartnady et al., 1985).

The Rehoboth Terrane is largely hidden beneath a more than 1 km thick cover of Nama Group sediments, as evident from drilling operations (Aquitaine, 1971). Crustal basement is mainly exposed in the north, in the Rehoboth basement inlier (RBI) complex. The terrane is subdivided by a strong magnetic lineament which separates into the Aroab and the Tses subprovince (Hoal et al., 1995). Age dating of exposed gneissic rocks, very similar to crustal basement rocks in the Kheis Magondi belt, in the Aroab subprovince resulted in ages around 1.8 Ga, indicating the existence of lithospheric material of the adjacent domain (Blignault et al., 1974; Hoal et al., 1995).

The Gibeon Kimberlite field is located in the Tses subprovince and has an extension of 70 Km from East to west and 110 km from North to south (Kurszlaukis et al., 1998). It consists of more than 75 kimberlite diatremes and associated carbonatite vents. On its southern edge, the Gross Brukkaros and the Blue Hills as well as associated smaller carbonatite dykes are located. Carbonatite eruptions were also triggered by the passing of the Discovery and eventually the Vema Hot spot (Davies et al., 2001).

Two samples used for this study were taken from the Kimberlite diatreme Louwrensia in the Gibeon kimberlite field and six stem from different carbonatite dykes, located close to the Gross Brukkaros (Fig.4.1).

## 4.4. Material and Methods

### 4.4.1. Sample description and Preparation

In total, this work investigates six crustal xenoliths from carbonatite diatremes around the Gross Brukkaros which accompanied kimberlite eruptions around 72.5 Ma ago (Davies et al., 2001) and one xenolith and one detritus sample (GLZ-1) from the Louwrensia kimberlite pipe in Gibeon. Samples from the Gross Brukkaros area were kindly provided by the University of Wuerzburg and collected and petrographically described by Rupprecht (unpublished results; PhD Thesis). Except for GLZ-1, all samples have an average diameter of 5 to 10 cm. The following petrographic descriptions of the carbonatite derived samples are based on the correspondent descriptions by Rupprecht (unpublished results; PhD Thesis).

KJA91-7 is a medium grained high grade-fenite from the carbonatite close to Jakkalsdraai. It does not show a sign of visible layering. The mineral assemblage is made up of aegirine-augite, alkali feldspar, plagioclase, calcite, apatite, ilmenite and magnetite.

KK3VB is a layered mafic granulite / garnet pyrobolite which is mainly made up of plagioclase, amphibole, clinopyroxene and garnets with diameters of up to 2 mm. Aluminosilicates and opaque minerals are visible as accessory phases.

K3e is a hornblende pyroxenefels from the carbonatite vent A2. The sample contains several xenoliths within the carbonatite matrix. Parts of the carbonatite matrix were crushed during the preparation process. K3eb is one of the xenoliths entrained in K3e and can be described as a clinopyroxene-amphibole felse with apatite and phlogopite as accessory mineral phases.

GLZ-2 is a high grade granulite, containing garnet and feldspar.

Except for the detritus samples, all samples were crushed in a SelFrag® Fragmentation system using voltages of 90 to 120 kV with a 1 mm built in sieve. Thereby a current runs between two electrodes in vessel filled with water in which the samples are placed. Using this technique allows the liberation of single grains, such as zircons, without cracking them as the minerals are separated along their grain boundaries. Contamination is kept to zero because the cleaning of the sample vessels is easy and very effective. Support for this efficiency may be the fact that not a single zircon grain was found in the amphibolites.

Crushing was followed by heavy liquid separation with Bromoform and sorting using a Frantz® magnetic separator. Amperage for the magnetic separation was adjusted up to 1.6 A with several steps in between. The least magnetic fraction, which contains the zircons, was treated with 6 M ultrapure HCl for 1 hour at 50°C to reduce the amount of apatite, which can easily be mistaken for zircon. Cleaned fractions were sieved with one time use fabric sieves, followed by hand picking with a stereo microscope.

Zircons were mounted on round holders with a diameter of one inch, embedded in epoxy and polished. As a preliminary work for laser ablation analyses, internal growth patterns of the zircons were revealed by cathodoluminescence imaging, using a Gatan MiniCL detector that is attached to a Jeol JSM-6490 electron microscope. Prior to this work, all mounts were coated with a thin layer of gold. We used a probe current of around 5 to 6 nA and a high voltage of 15 KV with a working distance of 15 mm.

#### **4.4.2. LA-SF-ICPMS U-Th-Pb analysis**

Prior to laser ablation analysis, gold coating was removed with ultrapure Ethanol. In order to remove any common lead from the surface that could stem from the preparation process, zircon mounts were cleaned with 2 % ultraclean nitric acid for 30s.

U-Pb dating was performed with a Thermo Finnigan Element 2 coupled to a Laser ablation system at the Goethe University in Frankfurt, Germany (GUF) in several sessions. For the majority of the samples, a New Wave UP213 Nd Yag laser with a teardrop shaped low volume sample cell was used, for the remaining samples (GLZ-1, GLZ-2, K3eb) a RESOLUTION M-50 193nm Excimer laser (Resonetics) was used. Samples ablated with the Resonetics M-50 laser were pre-ablated with 3 shots of the same energy as used for the following ablation in order to remove any surface contamination. Analysis was delayed to avoid the measurement of pre-ablated material. Spot sizes for all analyses varied from 20  $\mu\text{m}$  to 33  $\mu\text{m}$  and a fluence of 4-6 J  $\text{cm}^2$ . Laser holes were drilled with penetration depths of about 20  $\mu\text{m}$ . A detailed description of the analytical procedures used here for U-Pb dating is described in Gerdes and Zeh (2006; 2009). For internal standardization the GJ-1 zircon (Jackson et al., 2004) was used as primary standard and the Plešovice zircon (Slama et al., 2008) was used as a secondary standard to check the accuracy and quality of the analyses.

Offset for  $^{238}\text{U}/^{206}\text{Pb}$  ratios compared to the reference value of GJ-1 (Jackson et al., 2004) ranged in most sessions between 7 and 25%, whereas in two sessions, the offset was around 50%.

Multiple analyses of the Plešovice standard resulted in an age of  $346 \pm 8$  Ma and is in good agreement to reference values as published by Slama et al. (2008).

Data processing was performed, using an inhouse macro-based Excel® spreadsheet, created by A. Gerdes. The U-Pb data was usually corrected for common Pb using the measured Hg-interference corrected  $^{204}\text{Pb}$  signal and a Stacey and Kramers (1975) composition. However, for many analyses the  $^{204}\text{Pb}$  was so low that it was below detection limit. Age probability-density plots were created using the Excel® spreadsheet of Sircombe (Sircombe, 2004). Concordia diagrams were created, using Isoplot 3.7 (Ludwig, 2008). Some of the data points as listed in Table A.4.1, were saturated in the signal for  $^{238}\text{U}$  due to the usage of the counting mode, plotting above the Concordia line. These points were not considered for the Concordia diagrams.

#### **4.4.3. LA-SF-ICPMS Hf analysis**

Hafnium isotope measurements were performed with a Thermo-Finnigan Neptune multicollector (MC)-ICPMS at the Goethe University Frankfurt, coupled to New Wave UP213 Nd YAG laser (first part of the study) and a Resolution M-50 (Resonetics) 193 nm ArF excimer laser (CompexPro 102, Coherent) system, respectively, following the procedures described in Gerdes and Zeh (2006). Laser spots with diameter 40  $\mu\text{m}$  were drilled with a frequency of 5.5 Hz and an energy density of 6  $\text{J}/\text{cm}^2$  during 55 s of data acquisition. The 40  $\mu\text{m}$  Hf analysis spot was set on top or just next to the U-Th-Pb spot in the same growth domain as indicated by CL images. Penetration depths of the laser spots are in the range of about 40 to 50  $\mu\text{m}$ .

Data were processed by the adjustment of all analyses to a  $^{176}\text{Hf}/^{177}\text{Hf}$  isotope ratio of 0.282160 of reference standard JMC475. GJ-1 and Plešovice standards were measured in every measurement session to ensure high quality analyses. Average  $^{176}\text{Hf}/^{177}\text{Hf}$  isotope ratios of GJ-1 in 84 analyses were at  $0.282017 \pm 0.00007$  (2 sigma) and  $0.282490 \pm 0.000055$  (2 sigma) for 38 analyses of the Plešovice standard, which is in accordance to published reference values (Gerdes and Zeh, 2006; Slama et al., 2008).

$\epsilon_{\text{Hf}}(t)_{\text{initial}}$  values were calculated by first subtracting the amount of radiogenic  $^{176}\text{Hf}$  from the  $^{176}\text{Hf}/^{177}\text{Hf}$  ratios with the use of the corresponding age as obtained before by the U-Th-Pb analyses. Additionally,  $^{176}\text{Lu}/^{177}\text{Hf}$  and  $^{176}\text{Hf}/^{177}\text{Hf}$  ratios of 0.0336 and 0.282785 were used (Bouvier et al., 2008) along with a decay constant of  $1.867 \cdot 10^{-11}$  (average Scherer et al., 2001; Söderlund et al., 2004). Only datapoints with concordant ages (90 – 110% concordance) and small errors were considered for further interpretations. Data in table A.4.2 without U-Pb ages did not have a concordant age.

## **4.5. Results**

### **4.5.1. Zircon morphology**

Samples GLZ-1, GLZ-2, and KK3VB contained up to several thousand zircons, whereas KJA 91-7 contained up to one hundred and K3e contained only up to 40 zircons. Only two zircons were found in sample K3eb and none in KK3V.

Most grain sizes ranged from 50 to 150  $\mu\text{m}$ , a smaller number of single crystals were larger than 200  $\mu\text{m}$ . Most of the grains do not contain xenocrystic cores and are euhedral to subrounded. Inclusions in predominant oscillatory zoned zircons are rare but a substantial amount of grains are marked by a thin, bright illuminating rim which could be measured only in few cases. Recrystallized grains were observed only in very few crystals.

### **4.5.2. U-Pb age spectra**

We obtained a wide range of U-Pb ages from around 500 Ma up to 2.9 Ga (Fig.4.2, 4.3; Table A.4.1). Taking all samples together we obtained prominent age clusters with peaks at around 650 Ma, between 1.0 to 1.15 Ga, 1.2 to 1.4 Ga, and 1.7 to 1.8 Ga and four ages between 2.7 – 2.9 Ga. Sixty percent of the ages are between 1.0 and 1.4 Ga. However the samples vary individually.

Carbonatite sample K3e has major age peaks from 600 to 700 Ma, 1.1 to 1.25 Ga and an old component at 2.1 Ga with 14 concordant analyses. Carbonatite sample K3eb, which is an individual mafic component within sample K3e only yielded one concordant age at 1.1 Ga.

Most ages of sample KJA91-7 fall within the range of 1.2 or 1.3 to 1.4 Ga, with 60 concordant analyses.

Fig.4.2: U-Pb age distribution patterns for each individual sample. Zircons from carbonatite derived xenoliths (C-F) show in general a smaller age range with mid-Proterozoic ages, while the kimberlite derived xenolith record events from 0.5 to 2.9 Ga (B). The sample from the matrix of the kimberlite shows a broader range in ages, as a result of the incorporation of Nama shale sediment zircons (A).

The last remaining sample, originating from a carbonatitic dyke, is KK3VB with 102 concordant analyses and a major peak around 1.1 to 1.2 Ga and some minor occurrences of ages between 1.4 and 1.6 Ga.

Sample GLZ-1 from the matrix of the Louwrensia Kimberlite pipe, has prominent peaks in all age clusters as mentioned above with 80 concordant analyses, while the most prominent peak is around 1.0 to 1.2 Ga. Four zircons give the oldest ages of around 2.7 to 2.9 Ga, overlapping with the Archean ages of the granite cobbles from Dwyka tillites reported by Cornell et al. (2011). The cathodoluminescence images of our old zircons testify a magmatic origin.

The kimberlite derived crustal xenolith GLZ-2 has two major age groups at around 1.2 Ga and 1.8 to 1.9 Ga, while there are some minor additional peaks around 0.6 to 0.7 Ga, 1.4 Ga, 1.7 Ga and 2.0 to 2.3 Ga.

Where possible, xenocrystic cores and surrounding rims were both analysed. In sample KK3VB, the ages of the core yielded ages of 1.2 Ga to 1.3 Ga with corresponding rims of around 1.15 Ga. For samples K3e, KJA91-7 and GLZ-2, cores yielded ages of 1.3 and 1.5 Ga with rims around 1.2 and 1.3, respectively. Sample GLZ-1 zircon show larger age variation and core-rim age determinations yielded core ages of around 0.8, 1.0, 1.1, 1.5 and 1.9 Ga and corresponding rim ages of 0.5, 0.6, 1.0, 1.1 and 1.8 Ga.

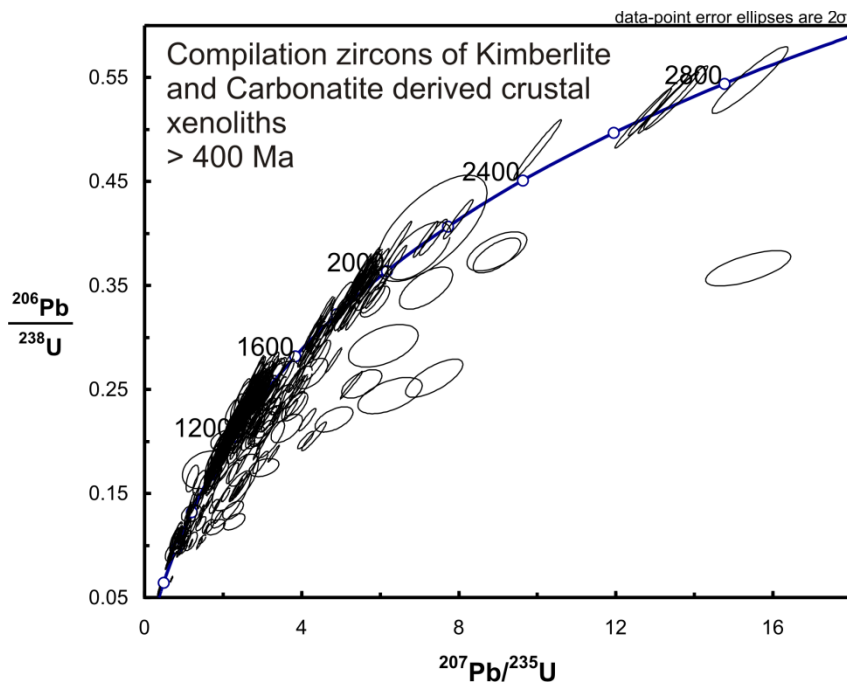

Fig.4.3 : Concordia diagram of all zircons from kimberlite and carbonatite derived xenoliths.

### 4.5.3. Hf isotopic composition

The data are given in Table A4.2 and shown in Fig.4.4 as  $\epsilon\text{Hf}(t)$  values plotted against the U-Pb ages of the zircons.

Measured  $^{176}\text{Hf}/^{177}\text{Hf}$  isotope ratios were calculated into  $\epsilon\text{Hf}(t)$  values by using the corresponding U-Pb age. Except for one data point, all data plot below the evolution line for the depleted mantle (present day  $^{176}\text{Hf}/^{177}\text{Hf}$  from (Chauvel and Blichert-Toft, 2001)), including the errors.

The majority of the analyses (~ 65%) are positive, with  $\epsilon\text{Hf}(t)$  above the CHUR line. Generally the  $\epsilon\text{Hf}(t)$  values increase from the Paleoproterozoic to the Mesoproterozoic, whereas the largest variation of the  $\epsilon\text{Hf}(t)$  from +14.5 to -21 can be observed close to the boundary to the Neoproterozoic.

$\epsilon\text{Hf}(t)$  values for GLZ-1 range from around -20 to +14, for GLZ-2 from -12 to +12, for KJA91-7 from +2 to +11, for KK3VB from -12 to 15, for K3e from -2 to +14 and for K3eb around +1.

The four Archean-aged zircons of the sample GLZ-1 have  $\epsilon\text{Hf}(t)$  values between +2 and -5. The age cluster between 1.7 and 2.2 Ga has  $\epsilon\text{Hf}(t)$  values ranging from +5 to -9 belonging to samples GLZ-1 and GLZ-2. Ages between 1.6 and 1.2 Ga are characterized by  $\epsilon\text{Hf}(t)$  values from +11 to -9, while there is a large vertical spread around 1.2 to 1.3 Ga with  $\epsilon\text{Hf}(t)$  values from +5 to -10, including all samples of this study except for K3eb. Proterozoic ages from 1.1 to 0.9 Ga are between +11 to +2  $\epsilon\text{Hf}(t)$  units and belong to sample GLZ-1, KK3VB, K3e and K3eb. The most recent ages from 0.9 to 0.5 Ga (GLZ-1, K3e) range between +8 to -15  $\epsilon\text{Hf}(t)$  units.

A positive linear correlation between U-Pb and Hf model age shows no visible Pb loss in the sample set used for this study (Fig.4.5).

## 4.6. Discussion

### *Provenance regions of the samples*

It is important to note that crustal xenoliths investigated in this study that stem from carbonatite eruptions report mainly a time span between 1 to 1.5 Ga, whereas the kimberlite pipe derived xenolith and one sample from the matrix of the Louwrensia Kimberlite pipe, show a broader range of crustal events.

K3e shows a different age spectra, with additional age peaks around 500 to 700 Ma, and one single age at 2.1 Ga. These additional age peaks cannot be found in the other xenoliths originated from the carbonatites. They represent zircons derived from the carbonatite itself as during the preparation process parts of the carbonatite matrix was crushed and mixed with the enclosed crustal xenoliths.

For this reason, the maximum possible age for the precursor sediments of the carbonatites derived xenoliths is around 1 Ga, whereas that of the kimberlite derived xenoliths is only about 600 to 700 Ma. The carbonatite derived xenoliths may come from a stratigraphically different crustal part than the kimberlite derived xenoliths. Also, the sedimentary precursors may have sampled material from a different hinterland.

The kimberlite matrix sample potentially collected all these various layers and rare Archean magmatic rocks from the crust. There may, however, also be a component incorporated from the Nama sediments. It also yielded a substantial number of zircons with ages between 0.5 and 0.8 Ga, the age of the Pan African Orogeny, in which the Damara belt was created. A Pan African component has not been reported so far from the Rehoboth province and the origin of these zircons may be from the Nama group shales whose debris was incorporated into the kimberlite matrix during eruption.

It has been shown in former studies of detrital zircons, that zircons are able to survive long distance transports over time (e.g. Morag et al., 2011). On the other hand, a former study has shown that even though zircons are capable of surviving such long transports, it does not necessarily mean that they are being transported far away (Klamma, Unpublished results; PhD Thesis). It is unlikely but it cannot completely be excluded that ages from sample GLZ-1 are not

made up of zircons from the Rehoboth Terrane itself but of neighbouring geotectonic domains such as the Kaapvaal craton.

### *Crust formation and recycling*

This new U-Pb and Hf data bring up new aspects about the framework of the lower crust beneath the Rehoboth Terrane, in particular about the framework beneath the Gibeon kimberlite field. The question if there is any evidence for the Kheis Orogeny in the crustal record studied is also addressed.

Taking the the average crustal  $^{176}\text{Lu}/^{177}\text{Hf}$  ratio of 0.0133 of Rudnick and Gao (2003) and projecting the Hf-isotope evolution back onto the depleted mantle, four periods of crustal growth (Fig.4.4) can be derived.

1. The oldest crustal components are represented by zircon with ages around 2.7 to 2.9 Ga and a Hf isotope composition similar to the primitive mantle at that time. Depleted mantle model ages range from 3.05 to 3.38 Ga.  $\epsilon\text{Hf}(t)$  values of around -12 show subsequent recycling of this crust at a time around 1.9 to 2 Ga.
2. Palaeoproterozoic to Mesoproterozoic zircon suggest that juvenile crust was extracted from a depleted mantle source around 2.3 to 2.7 Ga. The most positive  $\epsilon\text{Hf}(t)$  values of +5 yield Palaeoproterozoic grains. Recycling of this Palaeoproterozoic to Neoproterozoic crust during subsequent orogenic events is reflected by negative  $\epsilon\text{Hf}(t)$  values around -14 to -22 in 1.0 to 1.2 Ga zircon.
3. Most Mesoproterozoic zircons in the interval 1.3 to 1.5 Ga are characterized by positive  $\epsilon\text{Hf}(t)$  of +2 to +12 with a clear positive correlation between zircon age and  $\epsilon\text{Hf}(t)$  pointing to an important juvenile crust forming event at around 1.5-1.6 Ga. The steepening slope between 1.3-1.1 Ga towards more negative  $\epsilon\text{Hf}(t)$  is interpreted to reflect mixing of the juvenile and old crust during this time. It is worth noting that zircon affected by Pb-loss will also show a stronger decrease of the  $\epsilon\text{Hf}(t)$  with age as the postulated crustal evolution trend with a  $^{176}\text{Lu}/^{177}\text{Hf}$  ratio of 0.0113 (Rudnick and Gao, 2003). Juvenile growth of crustal material commenced around 1.8 to 1.9 Ga, whereas only few of

our data points are available from this event with  $\epsilon\text{Hf}(t)$  values corresponding to a depleted mantle source.

The most prominent cluster of points have  $\epsilon\text{Hf}(t)$  values are in the range of +5 to -3. The amount of ages in the range of 1.0 to 1.4 Ga make up about 60% of all measured data points overall and consist of data from all analyzed samples, whereas the major part stems from the sample KK3VB, a xenolith derived from a carbonatite vent near the Gross Brukkaros mountain, south of the Gibeon Kimberlite field.

4. Zircon formed in the late period of the Namaqua Orogeny at around 0.8 to 1.1 Ga, show  $\epsilon\text{Hf}(t)$  values of around +14 to -22, with a maximum of around +4 to +10, +12 consistent with formation of juvenile crust from a depleted mantle source, recycling of old crust and the mixing of both components to variable degrees. This is evident from three samples, whereas the major part is derived from the sample GLZ-1. This newly formed crust has experienced recycling during the build-up of the Damara belt at the time of the Pan African Orogeny around 0.5 to 0.6 Ga. This late stage recycling is evident from the carbonatite derived xenoliths K3e and the kimberlite derived detritus sample GLZ-1.

One sample, the matrix of the Louwrensia Kimberlite (GLZ-1), shows a large range in ages, with oldest ages from 2.7 to 2.9 Ga. These ages are in accordance with ages determined by Cornell et al. (2011) in zircons from granite boulders in Dwyka tillites from Rietfontein and by Van Schijndel et al. (2011a) from detrital zircons of the Rehoboth Basement Inlier. The  $\epsilon\text{Hf}(t)$  values are not very different to values for a primitive mantle at that time. Crustal growth may have commenced not too long before at around 3.1 Ga ago if these values are related to a depleted mantle. Cornell et al. (2011) determined the oxygen isotopes in their zircons, the  $\delta^{18}\text{O}$  values are close to the mantle which indicates an immediate derivation from mantle derived rocks.

Evidence for a major event around 1.8 to 1.9 Ga in the Rehobotian crust is most obvious in both kimberlite derived samples (GLZ-1 and GLZ-2). This peak coincides with the age of the Kheis Orogeny (Tinker et al., 2004).

Fig.4.4:  $\epsilon\text{Hf}(t)$  values and their corresponding U-Pb ages. Fields for crustal growth were calculated with a  $^{176}\text{Lu}/^{177}\text{Hf}$  of 0.0113 (Rudnick and Gao, 2003). The grey, blue, green and yellow field show juvenile crustal growth as well as crustal recycling and mixing of different crustal components.

Detrital zircons from a quartzite with a major peak around 1866 Ma are also well known from the Billstein Formation in the Rehoboth Basement Inlier to the north of Gibeon (Van Schijndel et al., 2011a). The  $\epsilon\text{Hf}(t)$  values for this age group range are mostly negative (with extreme values down to -15 and a peak at around -5), but there is also a minority with  $\epsilon\text{Hf}(t)$  up to +5 and an extreme value at +15). The debris from the Kheisian aged crust shows that it is a product of multiple stage crust recycling which was derived from a highly depleted mantle source. Calculated model ages point towards a primary source which may have originated in the late Archean.

## Crust and Mantle

Two major theories about the generation of continental crust over time are competing. Pulsed growth of large volumes of continental crust stands in contrast to a model that describes steady accumulation of continental crust (as summarized by Pearson et al. (2007)). Newer evidence for pulsed crustal growth comes from Pearson et al. (2007) who compared U-Pb zircon data from crustal rocks with the distribution pattern of  $T_{RD}$  ages (Rhenium depletion ages) from platinum-group alloys (PGAs) and peridotites. They found a good correspondence of large crustal and mantle events which is in accordance to the theory of pulsed growth of the continental crust. Further evidence for pulsed growth was found in  $^4\text{He}/^3\text{He}$  isotope ratios from ocean island basalts by Parman (2007).

With our new geochronological data from the Rehoboth crust and previously published age data for mantle events underneath the Rehoboth province (Hoal et al., 1995; Pearson et al., 2004; Janney et al., 2010; Luchs et al., submitted), we try to find further evidence for correspondence or disparity of major events (melting and / or reenrichment) in the mantle and the crust.

Fig.4.5 A linear correlation of U-Pb ages and model ages shows that there was hardly any lead loss. The four red ellipses mark the four phases of crustal growth as recalculated in Fig.4.3

The oldest U-Pb zircon ages from this data set and that of Cornell et al. (2011) and Van Schijndel et al. (2011a) would correspond to a 2.9 Ga Re-Os isochron age inferred by us from the Re-Os data set of Pearson et al. (2004) on garnet peridotites from the neighbouring pipe Louwrensia (see Luchs et al., submitted and Chapter 1). The Rehoboth crust and mantle would

be closely genetically related if both of our assumptions i) that the old zircons are derived from the Rehoboth crust and ii) that the 2.9 Ga Re-Os isochron exists, are correct. The zircon  $\epsilon\text{Hf}(t)$  values around zero and mantle values of  $\delta^{18}\text{O}$  additionally point to a close link between mantle and overlying crust.

Subduction and enrichment of the Rehoboth mantle at the time of the collision of the Rehoboth Terrane and the Kaapvaal craton around 1.8 Ga has been proposed by Luchs et al. ((submitted) and Chapter 3) from Lu-Hf isotope systematics of garnet peridotites with sigmoidal garnet REE patterns from Gibeon Townsland and Hanaus. The time of this enrichment event by melts or fluids is also seen in the U-Pb zircon ages which peak around 1.8 to 1.9 Ga. The zircons have a large spread of  $\epsilon\text{Hf}(t)$  with mostly negative values. This means major reworking of older crustal components (which may be as old as 2.5 Ga) at that period of time. Mixing of different crustal sources is the most probable reason for the vertical spread in  $\epsilon\text{Hf}(t)$  values at this time. The age pattern of Cornell et al. (2011) from granitic cobbles, separated from Dwyka tillites in Rietfontein show a distinctive gap between 1.4 and 2 Ga, which lead them to a geotectonic model for the evolution of the assembly of the southern African terranes in which the Kheis thrust complex formed at around 1.2 Ga. As our sample area is far more north of Rietfontain, the existence of such ages that correspond to the Kheis belt in our sample set could mean that the evolution of the crustal domains of the different areas inside of the Rehoboth Terrane could have been different. Another explanation would be that the sampling sites of the tillites were not affected by the enrichment event that affected the underlying mantle.

Our data shows a distinctive gap of ages between 1.4 and 1.7 Ga which is in accordance with the results of Van Schijndel et al. (2011a). They interpreted this time interval as a quiet some period within the Rehoboth Terrane without significant magmatism, which seems to be valid for at least a large part of the Terrane.

Becker et al. (2006) proposed a northeast-directed subduction underneath the Kalahari Plate, starting with tonalitic intrusions around 1.37 Ga, followed by the Namaqua Orogeny around 1.1 Ga. We have a large cluster of ages from 1.5 to 1.1 Ga which could be related to this event. The data stems from all of the samples, whereas a major part comes from one sample that derived from a carbonatite vent associated to the Gross Brukkaros and from one crustal xenolith collected on the Louwrensia kimberlite pipe. Juvenile crustal growth started around 1.4 to 1.5 Ga. This crust has been recycled until 1.0 Ga, which can be observed from the  $\epsilon\text{Hf}(t)$  values in

our data. At around 1.2 Ga, there is a large number of samples with a vertical spread in  $\epsilon\text{Hf}(t)$  values. At this time, terranes of the later created Namaqua belt started to accret along the western border of the Rehoboth Terrane. Preexisting crust from these terranes has probably been mixed with crust from the Rehoboth Terrane and created the vertical crust evolution array (Becker et al., 2006).

The matrix sample from the Louwrensia Kimberlite pipe and one xenolith from the carbonatite pipe K3e, have a larger zircon population with ages between 1.1 and 0.9 Ga and with  $\epsilon\text{Hf}$  values centering around +5 below the evolution curve for a depleted mantle. The ages correspond to the younger time of the Namaqua orogeny. Luchs et al. (submitted; see also Chapter 1) determined a mantle enrichment event underneath the Gibeon of 850 Ma which comes close to this event.

#### **4.7. Conclusions**

The Gibeon kimberlite field shows evidence for multiple large scale geotectonic events as recorded in the crustal xenoliths from carbonatite and kimberlite pipes and one sample collected from the detritus of the Louwrensia Kimberlite. It is also possible to make direct correlations of crustal events from this study to depletion and enrichment events in the mantle from a recent study (Luchs et al., submitted).

Our model for the evolution of the lower crust beneath Gibeon starts with the generation of Archean crust from a primitive mantle source which is in accordance to a new interpretation of Re-Os data (Pearson et al., 2004) by Luchs et al. (submitted) and recent studies from other regions of the Rehoboth Terrane (Cornell et al., 2011; Van Schijndel et al., 2011a), though it cannot be excluded that these zircons stem from the Kaapvaal craton as their model ages are in the range of the first crust generated in the Kaapvaal craton around 3.1 to 3.3 Ga. This episode is followed by juvenile crust generation around 2.3 to 2.7 Ga which was subsequently recycled during the attachment of the Rehoboth Terrane to the Kaapvaal craton around 1.8 to 1.9 Ga until it ended around 1 Ga. Recycling is supported by a Lu-Hf enrichment age of around 1.9 Ga of garnet peridotites from Gibeon (Luchs et al., submitted).

Crust generation around 1.2 to 1.5 Ga is probably related to a subduction process underneath the Kalahari Plate as proposed by Becker et al. (2006) and probably started around 1.8 Ga and marks the next greater crustal event within the southern African tectonic framework that did not affect the lithospheric mantle. Around 60 % of ages from this dataset lie in between this age range and support the significance of the event due to the high number of ages.

Juvenile crust was generated during the Namaquan Orogeny between 1.1 and 0.8 Ga which was subsequently recycled during the formation of the Damara belt at the time of the Pan African Orogeny.

Carbonatite and kimberlite derived xenoliths show slightly different age patterns, with a number of additional ages around 1.8 to 2.3 Ga for the latter. This age range is another confirmation for a palaeo-proterozoic Kheis Orogeny.

Our new crustal data, combined with geochronological data from garnet peridotites from Luchs et al. (submitted) further support the theory of pulsed crustal growth which is in contrast to a steady accumulation of newly grown crust through earth's history.

Our work on crustal xenoliths and a kimberlite matrix shows that the Gibeon volcanic field within the Rehoboth province is underlain by metamorphosed sediments which are not older than about 0.9 to 1 Ga without considering the age groups for the nama shale sediments. The metamorphosed sediments contain zircons from the two major tectonomagmatic events which were reported from outcrops to the north of the Gibeon field, namely of the Namaqua-Natal orogeny between 900 and 1200 Ma and from the Kheis-Maghondi event, mostly between 1700 – 1900 Ma (see compilation Janney et al., 2010). The sediments most have been deposited on older crust. The youngest possible age of this crust can be that of the Namaqua-Natal orogeny. It may be older and correspond to the Kheis-Maghondi event and it may even contain Archean components.

#### **4.8. Acknowledgements**

We owe thanks to H. Hoefler for assistance with the secondary electron microscope. A. Zeh is thanked for helpful discussions. For help during preparation, J. Heliosch and M. Krebs are thanked. This project was supported by the Deutsche Forschungsgemeinschaft, grant BR 1012/37-1.

## **Chapter 5:**

### **Lu-Hf, Sm-Nd and Sr isotope systematics of mantle xenoliths from Cabezo Negro de Tallante, Spain**

#### **5.1. Abstract**

We have investigated clinopyroxenes, orthopyroxenes and plagioclases of spinel / plagioclase peridotites from the neogene volcano Cabezo Negro de Tallante in the South eastern volcanic province (Spain) for the major and trace element (clinopyroxene, orthopyroxene and plagioclase), as well as isotope characteristics (clinopyroxenes, plagioclases) with special regards to the Lu-Hf, Sm-Nd and Rb-Sr isotope system.

Three types of trace element patterns in the clinopyroxenes can be distinguished: the first are slightly depleted in light rare earth elements (LREE) and slightly enriched in middle rare earth elements, the second have flat REE patterns and the third are highly enriched in LREE.

Lu-Hf isotope systematics of the clinopyroxenes point towards a depletion event that might have occurred around 550 to 600 Ma ago. Older components could still be available as the model age of the most radiogenic sample is nearly Archean. Sm-Nd isotope systematics of the same minerals scatter but might still have retained the age of depletion, with data points scattering around the age obtained from Lu-Hf.

Sr isotope data of clinopyroxenes and plagioclases differ, with the clinopyroxenes having lower values than the plagioclases. The plagioclases have an isotopic signature corresponding to the alkaline melts that transported the mantle nodules to the surface, which means that the isotopic ratios of the plagioclases might have been changed by the rising alkaline melts.

#### **5.2. Introduction**

The neogene alkaline basaltic volcanism in the South eastern volcanic province (SEVP) of Spain is related to a young extensional phase in connection with the relative movements between the African and Iberian plate. Numerous mantle xenoliths have been transported to the surface by

the rising alkaline melts and have been the subject for several studies (e.g. Kogarko et al., 2001; Beccaluva et al., 2004; Bianchini et al., 2011).

Bellon et al. (1983) determined the K-Ar age of these to 2.6 to 2.8 Ma. The basalts and their explosive counterparts were erupted onto Permian mica shists.

The basalts and their tuffs carry abundant spinel and plagioclase peridotites, partly with amphibole and phlogopite, orthopyroxenites and amphibole, plagioclase and clinopyroxene megacrysts as well as some minor amount of crustal xenoliths.

However, not much is known about mantle depletion or enrichment processes and their timing in the mantle underneath the SEVP. A recent study of Bianchini et al. (2011) points towards a depletion process in the Proterozoic. These processes are key aspects for the understanding of the evolution of the whole lithosphere as the Iberian continent has experienced a complex tectonic history, including subduction and an extensional phase.

In this work, major and trace element as well as an isotope study of mantle peridotites and their corresponding minerals from Cabezo Negro de Tallante are presented. This volcano is situated within the SEVP in the Betic Cordillera. Our aim is to characterize the mantle underneath the SEVP for PT conditions, trace element content and to determine the time of depletion as well as the time of mantle metasomatism by Lu-Hf and Sm-Nd and Rb-Sr isotope systematics respectively. Sr isotope systematics of clinopyroxenes and plagioclases should enable us to clarify if the both mineral phases are cogenetic.

### **5.3. Geological background and previous work**

Since the breakup of Gondwana, the African plate is showing a constant movement towards the north. It resulted in the convergence of the African and the Iberian plate, enclosing the Alboran microplate.

The subsequent evolution of the African-Alboran-Iberia region in the neogene is still highly disputed. Several models for the latest time span and the reason for the change from subduction like to intraplate like magmatism in the Alboran, the northern African and southern Spanish regions have been proposed from which we will only discuss the most important ones.

Eastward directed subduction of the Tethys slab is one possible scenario as proposed by e.g. Duggen et al. (2005). They suggested that slab derived fluids and melts caused subduction like magmatism. Roll back and delamination of subcontinental lithosphere is believed to be the process responsible for a westward migration of the subduction line, the extension of the basin and the upwelling of plume material, which is thought to have produced Si-poor and K-poor magmatism.

In contrast, Turner et al. (1999) suggest convective removal of lithospheric mantle beneath the Alboran basin to be the most likely process and to be responsible for extensional magmatism.

As an alternative scenario, the rising of a mantle diapir may have caused magmatism as proposed by Weijermars et al. (1985).

Fig.5.1: Map of the south-eastern coastline of Spain with the occurrences of neogene rocks that were emplaced into the Betic Cordillera. Marked in red are the alkali basalts together with Cabezo Negro de Tallante, from which the peridotites for this study were collected. Modified after Turner et al. (1999) and Venturelli et al. (1984).

Intraplate like magmatism also occurred in the south eastern coastline of Iberia, the south eastern volcanic province which forms part of the Betic cordillera.

The rocks related to the extensional phase of this African-Alboran-Iberian setting are made up of calc-alkaline, high-K calc alkaline and shoshonitic, ultrapotassic and alkaline basaltic volcanic rocks (see compilation Duggen et al., 2004).

Alkaline basalts are the most recent rocks in that area and were emplaced by phreatomagmatic eruptions, forming several small volcanic centers in the SEVP. Mantle xenoliths, megacrysts and crustal xenoliths, were entrained during the ascent of the magmas and can be collected on most of the outcrops.

Cabezo Negro de Tallante is one well-known volcano that was emplaced into the Permian mica schists 2.6 to 2.8 Ma ago (K-Ar; (Bellon et al., 1983)) and is situated close the small town of Tallante in the SEVP (Fig.5.1). A remarkable tuff layer can be found in between the basalts which has been deformed by volcanic bombs during the eruptions. The volcanic rocks contain numerous spinel and plagioclase lherzolites with specimen sizes up to 20 cm, as well as megacrysts and few crustal xenoliths.

Mantle nodules from Cabezo Negro de Tallante have been the subject for several studies. The major part of the peridotites are spinel or plagioclase lherzolites, with pressure and temperature ranges between 915 – 1030°C and 8 – 16 kbar respectively (Capedri et al., 1989; Beccaluva et al., 2004). Beccaluva et al. (2004) have subdivided the occurring peridotites into three groups: protogranular anhydrous spinel peridotites, amphibole/phlogopite-bearing harzburgites and orthopyroxenites with gabbroic/anorthosite veinlets and amphibole/phlogopite bearing clinopyroxenites.

They often contain pyroxenite or gabbroic anorthosite veinlets which are due to their deformation and textural state not related to the alkaline basalts (Dupuy et al., 1986).

Diffusion profiles in minerals of spinel lherzolites from Tallante by Kogarko et al. (2001) revealed that the peridotites ascended as a diapir with a velocity of 10 mm/a or less during a timeframe of about 3-4 Ma to a depths of 15 km in the crust before they were affected by the rising alkaline basalts that themselves have been molten in the garnet stability field (Dupuy et al., 1986). Mantle diapirism is also supported by investigations of spinel-pyroxene symplectites from Tallante (Shimizu et al., 2008).

They are thought to have been affected by two types of metasomatism, with one that has an anorogenic and another one with clear subduction related characters. This can be seen from the differently enriched Sr and Nd isotopic systematics of the xenoliths (Beccaluva et al., 2004).

Sr isotope ratios suggest that mantle xenoliths, megacrysts and the host alkaline basalts have different magmatic sources.

Based on major and trace element studies, a complex history of the upper mantle underlying Tallante has been suggested (Dupuy et al., 1986) with multiple melting events and metasomatism that may have produced heterogeneous peridotite portions within very short scale distances.

Hafnium isotope studies of mantle peridotites by Bianchini et al. (2011) revealed a Hafnium model age of the most radiogenic sample of 1.6 Ga for CHUR and 1.28 Ga for the depleted mantle. No further age determinations considering the mantle underlying the SEVP are available.

The crustal framework of the deeper crust is still unknown. U-Pb investigations of zircons from a graphitic schist of the Alpine Alpujarride nappe complex (Zeck and Williams, 2001) and a dacite from Cerro del Hoyazo (Zeck and Williams, 2002) revealed a wide age spectra of the crust from 320 Ma to 2.8 Ga with distinct age groups in between and a gap from 1.2 to 1.8 Ga. As both areas are located within the Betic Cordillera, these results can be regarded as being a potential reference for the makeup of the lower crust beneath Cabezo Negro de Tallante.

## **5.4. Materials and Methods**

Remaining fragments of the host alkaline basaltic rocks were removed with a stone saw from the plagioclase and spinel peridotites.

Thick sections of each sample were prepared for major and trace element analyses as well as for in-situ Strontium isotope ratio determinations.

### **5.4.1. Sample description**

We have collected plagioclase and spinel peridotites from the hill slopes of Cabezo Negro de Tallante with sizes mostly between 5 and 10 cm. One sample (CNTP-11) was more than 20 cm

in its longest extension. Alteration status for all samples can be described as fresh. From the collected samples, we selected 11 samples with differing clinopyroxene modal abundances with the intention to analyse a sample set for the Sm-Nd, Rb-Sr and Lu-Hf isotope systems with the largest possible spread in these element ratios.

The samples are spinel / plagioclase peridotites with olivine, orthopyroxene, clinopyroxene, spinel and plagioclase. The amount of clinopyroxene varies, with CNTP-2 having the least amount. Plagioclase could only be found in the samples CNTP-3, 5, 7, 9, 11, with only 3 to 5 grains per thin section, whereas spinel was present in all samples.

According to the classification scheme of Beccaluva et al. (2004), which is based on petrographic descriptions and major and trace element contents of the peridotite xenoliths from Tallante, all our samples can be assigned to the protogranular anhydrous spinel-peridotites with clinopyroxene rich lherzolites that can contain plagioclase.

#### **5.4.2. Major element analysis**

First paragraph of the following descriptions for major element analysis are taken from chapter 3.4.1 as there is no difference in the set-up, configuration and method for the analysis of the major elements.

Major elements were determined in olivine, orthopyroxene, clinopyroxene and garnet with a Jeol JXA 8900RL Superprobe with five spectrometers in WDS mode with a beam size of 3  $\mu\text{m}$ , an acceleration voltage of 15 kV and a probe current of 20 nA. For each sample and each mineral, three grains were analysed, with three analyses from core to rim to test for homogeneity. Peak measuring times varied between 20 to 30 s, background measuring times were 10 to 30 s. Standards were a mix of natural minerals and pure oxides and metals. CITZAF© algorithm by John T. Armstrong was used for matrix correction.

For the determination of Sr in Plagioclase, peak and background measurement times were increased to 40 s in order to lower the detection limit to about 400 ppm.

Calcium in olivine was determined as described by Koehler and Brey (1990) with peak and background measurement times increased to 120 s by using olivine SCKA as a secondary Ca standard. By applying this method, the detection limit for Ca was lowered to 30 ppmw (Koehler

and Brey, 1990). Average Ca concentrations in standard SCKA were around 524 ppm which is in perfect agreement to reference values as published by Koehler and Brey (1990).

#### **5.4.3. Trace element analysis**

Following descriptions for trace element analysis are taken from chapter 3.4.2 as set-up and configuration for the analysis are exactly the same.

Trace elements were analysed by Laser Ablation Inductively Coupled Plasma Mass Spectrometry (LA-ICPMS) using a Resonetics M-50 laser coupled with a Thermo-Finnigan® Element 2 at the Goethe University of Frankfurt.

Only unaltered and clear grains were considered for trace element analyses. For each sample, three grains of clinopyroxene and orthopyroxene were analysed with three laserspots from core to rim.

Analyses were performed with a spot size of 40  $\mu\text{m}$ , an energy density of c. 4-6  $\text{Jcm}^{-1}$  and a frequency of 10 Hz. We used as external standard a Nist 612 glass and CaO from microprobe analyses as an internal standard. Reference values for Nist 612 were taken from Pearce et al. (1997). The data were processed with the Gemoc GLITTER© software. USGS standard Bir-1G was always measured several times during an analytical session as secondary standard to monitor the machine performance and estimate the analytical precision and accuracy of the method. The obtained accuracy and precision for all analysed elements lie in the range of 2 to 15 %.

#### **5.4.4. Sr isotope analyses of plagioclase**

Strontium isotope analyses were performed using a Thermo Scientific Neptune multicollector ICPMS with Ni skimmer and sample cones coupled to a Resonetics M-50 laser. Spot sizes varied between 108 and 160  $\mu\text{m}$  with a repetition rate of 12 Hz at 110 mJ.  $^{87}\text{Sr}$  was corrected for interference with  $^{87}\text{Rb}$ . The limited grain size of the plagioclase grains made it impossible to make core-rim measurements with the laser spots necessary for achieving a signal that is high enough for a good signal. Nevertheless, where possible, several measurements per grain were carried out. Several analyses of Mir A as a standard were carried out and average  $^{87}\text{Sr}/^{88}\text{Sr}$  isotope ratios of 0.70308 were corrected to its reference value of 0.703096 as published by

Rankenburg et al. (2004). Additionally, Nist 610 was measured at the beginning and the end of the session.

Errors (2 sigma) for  $^{87}\text{Sr}/^{88}\text{Sr}$  range between 0.00003 to 0.00014.

#### **5.4.5. Isotope dilution (ID) analyses – Lu-Hf and Sr and Sm-Nd**

Based on their trace element patterns and the size of the hand specimens, samples were chosen for isotope dilution measurements considering Lu-Hf, Rb-Sr and Sm-Nd isotope systems.

Samples were crushed in a SelFrag® Lab system with a built-in sieve of 1 mm mesh size. Voltage was adjusted between 90 – 130 kV and electrode distance was reduced to a minimum level of 10 mm. Mineral separates were dried for several hours in a drying oven at 100°C followed by a separation with a Frantz magnetic separator and currents up to 1.6 A. Only clinopyroxenes with grain sizes smaller than 1 mm were considered during the handpicking process, using a stereomicroscope. Only clear fresh, unaltered and clean crystals were chosen for isotope dilution measurements.

Following descriptions for the preparation and the chromatographic separation are taken from chapter 3.4.3 with minor modifications as same procedures were used.

They were subsequently leached for 10 min in 2 M HCl which does not fractionate Hafnium or Neodymium isotopes as demonstrated by previous studies with 6 M HCl (DeWolf et al., 1996; Wittig et al., 2007). After rinsing with Milli-Q® H<sub>2</sub>O, samples were re-examined and then cleaned with Milli-Q® H<sub>2</sub>O in an ultrasonic bath for at least 1 hour. Each sample was weighed in and spiked with a  $^{176}\text{Lu}$ - $^{180}\text{Hf}$  and  $^{149}\text{Sm}$ - $^{150}\text{Nd}$  spike. Chemical separation of the desired elements was performed in one session ('batch') with 9 samples, including one column for a blank and one for standard BCR-1.

The samples were dissolved in 5 mL 3:1 HF (24 M): HNO<sub>3</sub> (15 M) solution in closed Savillex® teflon beakers at 120°C for 24 hours. Before fuming off, 150 µL of 11.6 M perchloric acid was added in order to prevent the formation of fluorides. After evaporation to dryness, the sample cake was re-dissolved in 6 M HCl and placed with the closed lid overnight on the hotplate at 120°C.

Samples were dried down and taken up in 3 M HCl in which 0.1 M ascorbic acid was added. Ascorbic acid is needed to reduce Fe<sup>3+</sup> to Fe<sup>2+</sup>, as Fe<sup>3+</sup> may block the resin in the column

(Muenker et al., 2001). Before loading the columns, each sample was centrifuged in order to remove any possible left over inclusions.

For the separation of Lu and Hf we followed the procedures of Muenker et al. (2001), using Eichrom® Ln.spec resin. The procedures of Muenker et al. (2001), were slightly modified by omitting the zirconium washing step and by using 2 M HF instead of 6 M HCl with 0.2 M HF for collecting Hf. Washing out the zirconium would result in a partial loss of Hf, which is not desirable considering the low amounts of Hf down to 10 ng.

Following the procedures of Pin and Zalduegui (1997), light rare earth elements (LREE) and Sr were separated from the dissolved sample using Biorad 50Wx8 resin, while the separation of Sm and Nd were performed in Ln.Spec resin, using the same columns and digestion batch that were used for the Lu and Hf separation.

Because of the small amounts of samples, column sizes were reduced from conventional sizes to 1 mL resin volume for Ln.Spec columns and 1.5 mL in case of Biorad 50Wx8 columns.

Samples were measured using a Thermo-Finnigan® Neptune MC-ICPMS at the Goethe University Frankfurt with Ni x cones following the method described in Schmidt et al. (2008). In case of Lu and Hf isotope measurements a CETAC Aridus™ nebulization system (ca. 70  $\mu\text{L}/\text{min}$ ) was used to enhance sensitivity (e.g., Hf, 500-800  $\text{Vppm}^{-1}$ ). A conventional glass spray chamber was used as a sample introduction system for Sm and Nd. Procedural blanks were generally below 25 pg for Hf, below 10 pg for Lu, around 20 pg for Nd, and around 13 pg for Sm. Mass bias was corrected using of 0.7325 for the  $^{179}\text{Hf}/^{177}\text{Hf}$  and 0.7219 for  $^{143}\text{Nd}/^{144}\text{Nd}$  (Blichert-Toft et al., 1997). The mass bias for Yb was monitored with  $^{173}\text{Yb}/^{171}\text{Yb} = 1.1248$  and used for interference correction of  $^{176}\text{Lu}$  and  $^{176}\text{Yb}$  on mass 176. JMC 475, Merck and Ames standards were measured during the analytical sessions to assure high quality isotope measurements of Hf and Nd isotopes. The comparison with published reference values (Blichert-Toft et al., 1997; Caro et al., 2006) shows that this was mostly achieved but a small offset correction had to be performed for Hf with isotope ratios of  $0.282137 \pm 0.000011$  for  $^{176}\text{Hf}/^{177}\text{Hf}$  before blank correction and  $0.51174 \pm 0.000025$  for  $^{143}\text{Nd}/^{144}\text{Nd}$  (Merck) and  $0.51197 \pm 0.000032$  for  $^{143}\text{Nd}/^{144}\text{Nd}$  (Ames).

Measurements of the standard BCR-1 yielded isotope ratios of  $0.282875 \pm 0.000011$  for  $^{176}\text{Hf}/^{177}\text{Hf}$  and  $0.512667 \pm 0.000025$  for  $^{143}\text{Nd}/^{144}\text{Nd}$ . The measured ratios are in good agreement with published data for Hf (see compilation Chu et al. (2002)) and Nd (see

compilation Yang et al. (2010)). The data were processed using in-house Excel® spreadsheets. Age calculations, following isotope ratio calculations were performed using Isoplot 3.7 (Ludwig, 2008).

Due to non negligible amounts of Sr in the blanks, measured  $^{86}\text{Sr}/^{87}\text{Sr}$  isotope ratios had to be corrected for their blanks. Routinely, after each sample measurement, blank concentrations were measured and subtracted automatically by the Sequence editor software of the instrument. Strontium standard solution SRM987 and measured  $^{86}\text{Sr}/^{87}\text{Sr}$  isotope ratios are in good agreement to literature data with ratios of  $0.710145 \pm 0.000011$  (Balcaen et al., 2005) after blank correction.

Errors for Lu-Hf and Sm-Nd are error propagations of the spike calibration and standard analyses of the corresponding isotope ratios. For  $^{176}\text{Lu}/^{177}\text{Hf}$  they are around 0.2 % (1 sigma), for  $^{176}\text{Hf}/^{177}\text{Hf}$  they range around 0.0019 % (1 sigma).  $^{147}\text{Sm}/^{144}\text{Nd}$  isotope ratios have an error around 0.2 % (1 sigma), whereas  $^{143}\text{Nd}/^{144}\text{Nd}$  has an error of around 0.0023 % (1 sigma).

$^{87}\text{Sr}/^{88}\text{Sr}$  isotope ratios are afflicted by errors between 0.001 to 0.002 % (1 sigma).

## 5.5. Results

### 5.5.1. Pressure and Temperature estimates

We used the two pyroxene thermometer of Brey and Koehler (1990) in combination with the Ca in olivine barometer of Koehler and Brey (1990) to determine pressures and temperatures of crystallization. The results are given in Table 5.1 and shown in Fig. 5.2. Temperatures for all samples range between 900 and 1000°C and pressures from 7 to 20 kbar. Three samples plot within an area around 900 to 920°C and pressures between 7 to 10 kbar, five samples have temperatures from 940 to 960°C and pressures from 12 to 15 kbar, whereas the remaining three samples plot around 980°C with pressures around 16 to 20 kbar, following a smooth trend that does not correspond to a geothermal gradient.

A previous study of mantle xenoliths from Cabezo Negro de Tallante of Capedri et al. (1989) revealed pressures and temperatures around 8 to 15 kbar and 900 to 1050°C, giving a much

steeper trend. They used the pressure dependent thermometer of Nickel et al. (1985) and the barometer of Mercier (1980).

Table 5.1: Geothermobarometrical data, isotope characteristics and classification from the clinopyroxenes of the analysed samples.

\* calculated by the concentrations of Rb and Sr as determined by LA-ICPMS and their relative isotopic abundances

<sup>1</sup> from Beccaluva et al. (2004) and Bianchini et al. (2011);  $^{176}\text{Hf}/^{177}\text{Hf}$  as given by Bianchini et al. (2011)  $^{176}\text{Lu}/^{177}\text{Hf}$  calculated from the Lu and Hf concentrations as given by Beccaluva et al. (2004) and the natural abundance of the corresponding isotopes

Pressures as determined by Mercier (1980) are affected by a degree of uncertainty as the aluminum isopleths in the spinel stability field are not pressure dependent but only dependent on the temperature (Sachtleben and Seck, 1981).

Fig.5.2: Pressures and temperatures as calculated by the two pyroxene thermometer of Brey and Koehler (1990) and Ca in olivine barometer of Koehler and Brey (1990) of this study (as marked by the diamond symbols) in comparison to P, T estimates as published by Capedri et al. (1989) (circles).

### 5.5.2. Plagioclase major element compositions

Plagioclases were measured from core to rim for samples CNTP-3, 5, 7, 9 and 11. The results are presented in Table A5.1 and Fig.5.2. They are variable in their Albite and Anorthite contents, with CaO/(CaO/Na<sub>2</sub>O) compositions ranging from around 0.55 to 0.72. Core and rim compositions are very similar for all samples except for CNTP-7 with one grain having values from 0.55 to 0.61.

Fig.5.3: SrO concentrations as a function of the amount of Anorthite of the plagioclases analysed by Laser ablation ICPMS. Different colors of the diamond symbols are corresponding to the different types of samples, as defined earlier.

CNTP-5 and CNTP-11 have slightly higher Anorthite contents than CNTP 3, 7 and 9 with values from 0.65 to 0.72 in contrast to 0.55 to 0.63. SrO contents range from about 0.2 to about 0.18 wt%.

### 5.5.3. Trace elements

Trace elements were determined in clinopyroxene and orthopyroxene. They are given in Table A5.2 and shown as REE and extended trace element patterns in Fig 5.4 and Fig. 5.5.

We distinguish three types of rare earth element patterns which are not correlated with pressure and temperature.

Fig.5.4: Rare earth element concentrations of the analyzed samples normalized to chondrite (McDonough and Sun, 1995). Three types of REE patterns are distinguished. Samples in green (type 1) have elevated MREE and slightly depleted LREE. Red lines correspond to samples with mostly flat REE patterns (type 2), while the blue sample shows highly elevated LREE contents (type 3).

Type one (shown in shades of green colors in Fig. 5.3) has elevated MREE and comparatively lower light and heavy REE, consisting of seven samples. Four out of these seven samples have strong Eu anomalies due to the presence of plagioclase.  $Sm_N/Yb_N$  ratios range from 0.98 to 1.49, indicating a minor enrichment for middle rare earth elements. Light rare earth elements show signs of minor depletion with  $La_N/Yb_N$  element ratios from 0.28 to 0.73.

Type two comprises three samples, shown in red colors here. The REE abundances are lower compared to type 1 and the patterns of two of the samples gently increase from Lu towards the LREE.

Fig.5.5: Extended trace element patterns of the three types of samples as distinguished by their REE patterns. Th and U contents vary by a factor of around 10 for all samples. Concentrations were normalized on C1 (McDonough and Sun, 1995).

An exceptional sample is sample CNTP-7 as shown in blue which defines type three. Most MREE and HREE overlap with Type 1 but the MREE increase steeply from Eu onwards to La which has a more than 60 times chondritic abundance.

Extended trace element patterns of the clinopyroxenes for all samples reveal elevated thorium and uranium contents with a scatter by a factor of 10, which is in accordance to published values of additional samples from Tallante by Rampone et al. (2010). Minor to strong negative Sr anomalies can be assigned to all samples of the first type. One sample of the second type shows a minor to negligible negative strontium anomaly, whereas the remaining two samples even have a slightly positive peak for strontium.

Hafnium contents range from +4 to +10 for all samples, except for sample CNTP-2 that has the lowest abundance of hafnium with a value below 1 to chondrite.

#### **5.5.4. Isotope systematics**

##### 5.5.4.1. Lutetium-Hafnium

The analytical data are given in Table 5.1 and shown in Fig.5.6 in an isochron diagram.

$^{176}\text{Lu}/^{177}\text{Hf}$  ratios are generally very low, with ratios around 0.03 for six samples and 0.08 for one sample (CNTP-2), while  $^{176}\text{Hf}/^{177}\text{Hf}$  ratios for six samples plot from 0.2832 to 0.2836 and for one sample (CNTP-2) at higher values around 0.2849. No obvious correlation regarding time constraints between all of the samples is possible due to scattering of the datapoints and the limited range in  $^{176}\text{Lu}/^{177}\text{Hf}$ .

All analysed clinopyroxene separates show radiogenic Hf isotopic compositions with  $\epsilon\text{Hf}$  values around +25 which is higher than the present day value for the depleted mantle (Chauvel and Blichert-Toft, 2001). One sample (CNTP-2) is much more radiogenic, having an extremely high  $\epsilon\text{Hf}$  value of around +75 (Fig.5.7).

Fig.5.6: Lu-Hf isotope characteristics of the clinopyroxenes of seven samples analyzed from the samples of this study. Most samples are in the  $^{176}\text{Lu}/^{177}\text{Hf}$  range around 0.02 to 0.04 and between 0.2832 and 0.2836 for  $^{176}\text{Hf}/^{177}\text{Hf}$ . Only one sample plots higher for both isotope ratios.

Model ages, considering CHUR and the depleted mantle as the source of melt extraction result in negative values due to the fact that most  $^{176}\text{Lu}/^{177}\text{Hf}$  ratios of the samples are smaller than the  $^{176}\text{Lu}/^{177}\text{Hf}$  ratio of the respective reservoir. Positive model ages could therefore be calculated for only two samples, with only one (CNTP-2) giving a possible meaningful model age of 2.0 and 2.2 Ga for the depleted mantle and CHUR respectively.

Fig.5.7: Hf versus Nd of own data (diamonds) and data from Bianchini et al. (2011) (circles). The mantle array was calculated, according to Vervoort et al. (1999).

#### 5.5.4.2. Samarium-Neodymium

Isotope ratios of  $^{147}\text{Sm}/^{144}\text{Nd}$  and  $^{143}\text{Nd}/^{144}\text{Nd}$  are given in Table 5.1 and are visualized in Fig.5.8. There is no obvious linear correlation of the  $^{147}\text{Sm}/^{144}\text{Nd}$  and  $^{143}\text{Nd}/^{144}\text{Nd}$  isotope ratios when plotted into an isochron diagram. Only a rough trend can be obtained that does not allow precise isochron calculations. The projection of a 550 Ma reference isochron into the diagram shows that the data scatters around the projection. The scatter could be related to the narrow spread of  $^{147}\text{Sm}/^{144}\text{Nd}$  isotope ratios or that the samples have experienced a minor enrichment that was not able to overprint the age of depletion.

Radiogenic neodymium isotope contents in the samples are moderate with  $\epsilon\text{Nd}$  values ranging from +6 to +13.  $^{147}\text{Sm}/^{144}\text{Nd}$  isotope ratios for all samples show a small spread, with ratios from 0.14 to 0.24. In contrast to the results for Lu-Hf, sample CNTP-2 does not show extraordinary

high radiogenic  $\epsilon\text{Nd}$  values. In this case, the Sm-Nd and Lu-Hf isotope system seem to be decoupled (see Fig.5.7).

Fig.5.8: Sm-Nd isochron diagram with a reference isochron of 550 Ma

#### 5.5.4.3. Strontium isotopes in clinopyroxene

The results are given in Table 5.2 and shown Fig.5.9. Only five samples could be analysed because of analytical problems (strong decrease of the signal during autosampler mode).  $^{87}\text{Rb}/^{86}\text{Sr}$  ratios were calculated based on the corresponding concentrations as determined by LA-ICPMS. Four samples have calculated  $^{87}\text{Rb}/^{86}\text{Sr}$  ratios between 0.0008 to 0.005, while an additional sample is around 0.019.

$^{87}\text{Sr}/^{86}\text{Sr}$  ratios vary, two samples have extreme  $^{87}\text{Sr}/^{86}\text{Sr}$  ratios at 0.70210 and 0.70364, while three samples are in a very restricted range from 0.70262 to 0.70277. Any age correlations using

the isochron method are not applicable as the range is very narrow and no obvious trends or other correlations are visible.

#### 5.5.4.4. Strontium plagioclase

The results are given in Table 5.2 and initial values are shown in Fig.5.9. Strontium isotope ratios could successfully be measured in-situ by laser ablation ICPMS in plagioclase of five samples.

Sample	$^{87}\text{Rb}/^{86}\text{Sr}^*$	$^{87}\text{Sr}/^{86}\text{Sr}_{\text{Rb}}$	$^{87}\text{Sr}/^{86}\text{Sr}_{\text{Initial (600 Ma)}}$

\* calculated

Table 5.2: Sr isotope systematics of the plagioclases.  $^{87}\text{Rb}/^{86}\text{Sr}$  and  $^{87}\text{Sr}/^{86}\text{Sr}_{\text{Initial}}$  ratios were calculated by the amount of Rb in the individual sample and based on an assumed equilibration age of around 600 Ma for the latter.

Strontium concentrations range from several hundred ppm up to 1300 ppm. Unfortunately, the Rb-Sr isotope systematics of clinopyroxenes could not be determined in the same samples by

solution MC-ICPMS because of analytical problems (strong decrease of the signal during autosampler mode) except for sample CNTP-5.

Where possible, several grains per sample have been measured. The  $^{87}\text{Sr}/^{86}\text{Sr}$  isotope ratios range between 0.70258 up to 0.70480. Calculated  $^{86}\text{Rb}/^{87}\text{Sr}$  ratios are range in most cases from 0.0044 to 0.0732 with two exceptions showing values higher than 0.5

Fig.5.9: Initial  $^{87}\text{Sr}/^{86}\text{Sr}$  isotope ratios of plagioclases and clinopyroxenes as calculated for  $t = 600$  Ma, with the latter plotting in general in lower values than for the clinopyroxenes.

## 5.6. Discussion

### *Trace element characteristics*

The plagioclase and spinel peridotites from Tallante analysed here contain a complex heterogenous record in their trace element patterns and isotopic compositions, even though they all stem from the same sample site at Cabezo Negro de Tallante.

The volcanic eruptions have transported mantle nodules with mostly similar chemical trace element compositions from different depths to the surface. Three types of rare earth patterns could be distinguished. Type 1 has slightly depleted LREE contents relative to its slightly elevated MREE. Type 2 shows flat REE patterns, while type 3 is highly enriched in LREE but the MREE and HREE follow the patterns of type 1.

Most samples show distinctive negative peaks for Ti and some show less pronounced negative anomalies for Zr.

These features in the trace element patterns of clinopyroxene in spinel peridotites have been interpreted in a former study as a worldwide distinct layer in the upper mantle which is depleted in high field strength elements (Rampone et al., 1991; Hellebrand et al., 2005). Rampone et al. (1991) showed that positive titanium and zirconium anomalies in corresponding trace element patterns of orthopyroxene compensate the depletion of the HFSE in clinopyroxene and thus no such depleted layer in the upper mantle exists. Furthermore, a depletion of HFSE in clinopyroxene would mean that a non negligible portion of hafnium is in the corresponding orthopyroxenes and that it would have to be considered for hafnium isotope analyses, depending on the modal amount of orthopyroxene in the peridotite. On the other hand Choi et al. (2010) have shown that the amount of Hf in orthopyroxene is insignificant for spinel peridotites. All of our clinopyroxenes show a depletion of titanium with a positive Ti peak in the patterns of the corresponding orthopyroxenes (Fig.5.10). A stronger negative zirconium anomaly in the clinopyroxene is only visible for CNTP-2 and 3 and minor to negligible negative zirconium anomalies are visible for the rest of the samples. Positive zirconium anomalies in orthopyroxene can be found in all samples. The same systematics can be found for Hf, with positive anomalies in orthopyroxene and negative anomalies in the corresponding clinopyroxene, meaning that an age calculated for these samples which is only based on the analysis of clinopyroxene is only a minimum age and must be slightly older, according to the modal abundance of orthopyroxene.

Fig.5.10: Trace element concentrations of clinopyroxene and orthopyroxene normalized to chondrite (McDonough and Sun, 1995) with visible negative Zr and Ti anomalies for the clinopyroxene and corresponding positive Zr and Ti anomalies for orthopyroxene.

In order to visualize depletion or enrichment trends of trace elements, we have normalized selected trace elements of our samples to the sample Vitim 314-56 (Ionov et al., 2005) which we consider as a primitive sample (Fig.5.11). Based on the HREE, we have retraced the former state of trace element partitioning, as indicated by the colored fields.

LREE are elevated for all three sample types, as indicated by the arrows in blue, green and red.

Group 1 and 3 samples are slightly elevated for the MREE, whereas group 2 samples plot around 1 or slightly below. Hf does not seem to be enriched except for minor additions to CNTP-7 and CNTP-9. Considering that some Hafnium is retained in orthopyroxene, whole rock contents of Hf could be higher or in extreme cases even enriched. For Sm and Nd, obvious enrichment can only be seen for sample CNTP-7. This means that age correlations for all other samples, except for CNTP-7, considering the Sm-Nd isotope system could be related to the age of depletion unless there was a fractionation or other disturbances of the system.

Fig.5.11: Trace elements normalized to corresponding clinopyroxene concentrations of the primitive sample Vitim 314-56 (Ionov et al., 2005). The green arrow displays enrichment relative to Vitim 314-56 for group 1 samples, the red arrow displays enrichment for group 2 samples and the blue arrow if for the group 3 sample.

### *Time constraints*

We have analyzed Hafnium isotope systematics of clinopyroxenes in order to calculate the timing of mantle depletion. Our main assumption was that clinopyroxene is the main carrier of trace elements in the spinel / plagioclase lherzolites. Our samples plot in a very narrow range for  $^{176}\text{Lu}/^{177}\text{Hf}$  and  $^{176}\text{Hf}/^{177}\text{Hf}$  ratios for most samples, and are thus very restricted in their spread.

Initial  $^{176}\text{Hf}/^{177}\text{Hf}$  values of the clinopyroxenes were calculated in order to determine similar mantle sources to the melt extracted (Fig.5.12). Three samples out of this dataset (all type 1; CNTP-5,9,11) and one sample (TL1) that was published earlier in Bianchini et al. (2011), stem from the same mantle source when corrected for radiogenic  $^{176}\text{Hf}$  contents with an estimated depletion age of around 600 Ma, which can be regarded as a reasonable age for the correction as this is the timing of the assembly of Gondwana.

Only  $^{176}\text{Hf}/^{177}\text{Hf}$  ratios from the sample published by Bianchini et al. (2011) were available. The corresponding  $^{176}\text{Lu}/^{177}\text{Hf}$  ratios were calculated from the content of Lu and Hf and the abundance of  $^{176}\text{Lu}$  and  $^{177}\text{Hf}$ , which creates a large error for the ratio but enabled us to use it for our age calculations.

Fig.5.12:  $^{176}\text{Hf}/^{177}\text{Hf}_{\text{initial}}$  ratios for all samples of this study and one sample (TL16) of Bianchini et al. (2011) as corrected for 600 Ma.

Present day  $^{176}\text{Hf}/^{177}\text{Hf}_{\text{initial}}$  values of these samples are around 0.28303 to 0.28304 which correspond to around + 20  $\epsilon\text{Hf}$  units. A correlation of these samples in an isochron diagram resulted in an age of around 543 Ma, with a large error, due to the narrow  $^{176}\text{Lu}/^{177}\text{Hf}$  range (Fig.5.13) and the high error of the  $^{176}\text{Lu}/^{177}\text{Hf}$  ratio for sample 'TL1'. The elevated  $\epsilon\text{Hf}$  initial value of around + 22 points towards a highly depleted mantle as the source of melt extraction. Because of the trace element characteristics of corresponding clinopyroxenes and

orthopyroxenes, as mentioned before, the real age must be slightly older, depending on the modal amounts of orthopyroxene in the individual samples.

Another two samples from the dataset published in Beccaluva et al. (2004) and Bianchini et al. (2011) show a good agreement of initial  $^{176}\text{Hf}/^{177}\text{Hf}$  isotopic compositions, which supports the idea of melt extraction around 550 to 600 Ma.

Fig.5.13 Lu-Hf reference Isochron of 543 Ma for three samples from this study and an additional one from Bianchini et al. (2011), with no errors displayed for the latter (see text).

Our remaining three samples do not show any correlation of initial values (0.2829 to 0.2833) or model ages and show that the mantle underneath Tallante seems to be very heterogenous with respect to its isotopic composition. The sample with the highest  $^{176}\text{Lu}/^{177}\text{Hf}$  ratio shows initial  $^{176}\text{Hf}/^{177}\text{Hf}$  ratios that cannot be correlated to any other sample and can therefore not be accounted for any isochron calculation in this dataset.

Except for CNTP-5 and CNTP-2, all other samples have  $^{176}\text{Lu}/^{177}\text{Hf}$  values lower than the chondritic value or the depleted mantle and therefore result in negative model age. The most primitive sample of this dataset (CNTP-2) with very low Hafnium contents (0.16 ppm) is very radiogenic for Hafnium and has a Proterozoic model age for CHUR with 2.27 Ga and 1.97 Ga for the depleted mantle, suggesting an ancient mantle component. CNTP-5 has a negative model age for the depleted mantle but a model age of 1.11 Ga for CHUR.

As described before, Nd was slightly affected by enrichment due to mantle metasomatism. Isotope systematics of Sm and Nd therefore scatter and no reliable age for depletion or enrichment can be obtained. Nevertheless, a rough trend with an age of possibly 550 Ma between the data points can be correlated. Possibly this trend can be correlated to a depletion, given that the enrichment of Nd was not high enough to overprint the timing of depletion.

Similarities between the Ronda peridotite and different other European localities have been discussed in several other studies (e.g. Beccaluva et al., 2004; Bianchini et al., 2011). It has been shown by Beccaluva et al. (2004) that there is a great isotopic overlap of the Tallante anhydrous xenoliths, the Ronda peridotites (Reisberg et al., 1989), the Vulture peridotite xenoliths (Downes et al., 2002), Massif Central peridotite xenoliths (Downes and Dupuy, 1987; Zangana et al., 1997), Sardinia peridotite xenoliths (Beccaluva et al., 2001), Pyrenean peridotites (Downes et al., 1991) and the Lanzo Peridotites (Bodinier et al., 1991) concerning Neodymium and Strontium isotopic signatures. Multiple depletion events of the Rhonda peridotite have been dated to mid-Proterozoic ages ( $T_{RD}$ ) by Re-Os in-situ laser ablation ICPMS analyses of sulfides (Marchesi et al., 2010). The existence of mantle components with similar ages underneath the SEVP are indicated by sample CNTP-2 with Hf model ages of 2.3 for CHUR and 2.0 for the depleted mantle and another sample from a study of Bianchini et al. (2011) with a Hf model age of 1.6 Ga for CHUR and around 1.2 Ga for the depleted mantle. Radiogenic Neodymium isotope systematics of different European localities that have been summarized by Downes (2001) may indicate a late Proterozoic to early Palaeozoic depletion event but are considered to be more a mixed signature of depleted and enriched xenoliths. Therefore the timing of depletion is estimated based on Os isotope systematics to range from 1.2 to 2 Ga.

### *Nature of metasomatism*

Trace element enrichment due to mantle metasomatism can be seen from the trace element patterns of the clinopyroxenes by normalizing on a primitive spinel peridotite, which was for our samples a primitive sample from Siberia, referred to as Vitim 314-56 by Ionov et al. (Ionov et al., 2005). A LREE enrichment has affected Nd compositions which are elevated in comparison to the corresponding HREE. Beccaluva et al. (2004) have differentiated between anorogenic and subduction related metasomatism of samples from Cabezo Negro de Tallante. Metasomatism was expressed in elevated  $^{87}\text{Sr}/^{86}\text{Sr}$  and  $^{143}\text{Nd}/^{144}\text{Nd}$  isotopic ratios. They found that a melt, undersaturated in silica produced typically  $^{87}\text{Sr}/^{86}\text{Sr}$  ratios between 0.70213 and 0.70476 and  $^{143}\text{Nd}/^{144}\text{Nd}$  ratios between 0.51339 and 0.5125. Metasomatism due to subduction with oversaturated silica characteristics is expressed in isotope ratios between 0.70672 and 0.70856 for  $^{143}\text{Nd}/^{144}\text{Nd}$  and 0.51213 to 0.51211 for  $^{87}\text{Sr}/^{86}\text{Sr}$ . As already seen from the elevated light rare earth element contents, a minor enrichment has affected samples used for this study. Further confirmation comes from isotope analysis of clinopyroxene and plagioclase for Strontium, Samarium and Neodymium that are within the range as defined for anorogenic metasomatism by Beccaluva et al. (2004).

Correction of the clinopyroxenes for  $^{87}\text{Sr}/^{86}\text{Sr}$  ratios for radiogenic  $^{87}\text{Sr}$  due to the decay of  $^{87}\text{Rb}$  for the calculation of  $^{87}\text{Sr}/^{86}\text{Sr}_{\text{initial}}$  values for 600 Ma, has only a minor effect as the amount of Rb in most samples is nearly negligible. Four samples change in the fifth decimal place, whereas for one sample with the highest  $^{87}\text{Rb}/^{86}\text{Sr}$  ratio, the change is on the third decimal place.  $\epsilon\text{Sr}_{\text{initial}}$  values are in the range between +45 and +69.

Plagioclase in anhydrous spinel peridotites are described as being the product of reequilibration of spinel under new P, T conditions (Bianchini et al., 2011). Therefore  $^{87}\text{Sr}/^{86}\text{Sr}_{\text{initial}}$  ratios of clinopyroxenes and plagioclases can be compared if corrected for the same time since the last reequilibration.

Plagioclases corrected for radiogenic  $^{87}\text{Sr}$ , due to the decay of  $^{87}\text{Rb}$  for 600 Ma, changes the  $^{87}\text{Sr}/^{86}\text{Sr}_{\text{initial}}$  values mostly in the fourth digital place, ranging from 0.70253 up to 0.70478. In two samples, there are two groups of plagioclase grains within one sample, having different  $^{87}\text{Sr}/^{86}\text{Sr}_{\text{initial}}$  ratios. In CNTP-5 one group gives low values of 0.7034 and the other, 0.7047. For

CNTP-3, the lower values range from 0.7025 to 0.7036 and the higher have 0.7044. Plagioclases from sample CNTP-7 with highly enriched LREE in the clinopyroxenes also have high  $^{87}\text{Sr}/^{86}\text{Sr}_{\text{initial}}$  values of 0.70478.

In general, Strontium isotope ratios of the plagioclases are elevated in comparison to the isotope dilution measurements of the clinopyroxenes. For sample CNTP-5, corresponding  $^{87}\text{Sr}/^{86}\text{Sr}_{\text{initial}}$  ratios of clinopyroxene mineral concentrates are considerably lower with 0.70193.

$^{87}\text{Sr}/^{86}\text{Sr}$  isotope ratios of the alkali basalts from Cabezo Negro de Tallante have an average value of 0.70437, as determined by Capedri et al. (1989). It is therefore possible that the plagioclases of CNTP-7, CNTP-5 and CNTP-3 have been affected by the rising alkali basalts and changed their isotopic signature according to the infiltrating melts, whereas for CNTP-3 and CNTP-5, not all of the analyzed spots on the grains have such elevated values.

Kogarko et al. (2001) analyzed plagioclases of mantle xenoliths from Cabezo Negro de Tallante for Ca and Na compositions from core to rim. The cores of the plagioclases were more Na rich than the outer rim, being more calcic. Based on one concentration profile of their work, the rims have diameters around 10 – 20  $\mu\text{m}$ . Due to the large diameter of the laser spots ( $> 100 \mu\text{m}$ ) that we used in this study to determine Sr isotope systematics, rim composition could theoretically only be measured if the crystal was cut in the right orientation. Based on our results for major element compositions for the plagioclases, we do not see core-rim differences for the individual grains as described by Kogarko et al. (2001). Only for sample CNTP-7, the amount of SrO varies slightly with two points being slightly more rich in Anorthite, which is not expressed in  $^{87}\text{Sr}/^{86}\text{Sr}$  isotopic ratios.

## 5.7. Conclusions

New Lu-Hf, Sm-Nd and Sr isotopic determinations have been carried out to shed new light into the development of the mantle underneath the SEVP and to reveal the timing of depletion and enrichment.

Three types of rare earth element patterns are characteristic for the clinopyroxenes in this study, with an enrichment of light rare earth elements to different degrees for all three types. This

enrichment can also be detected from  $^{87}\text{Sr}/^{86}\text{Sr}$  and  $^{143}\text{Nd}/^{144}\text{Nd}$  isotope systematics and is related to anorogenic metasomatism as described by Beccaluva et al. (2004).

Our new studies of Lu-Hf isotope systematic suggest that the xenoliths sampled stem from several mantle domains with different geochemical characteristics and different timings of depletion.

Correlation of a group of samples indicates extraction during the Caledonian Orogeny, whereas two more samples suggest depletion in mid to late Proterozoic times. The latter are in agreement other localities all over the European continent (Beccaluva et al., 2001; Downes, 2001; Bianchini et al., 2007).

The timing of subsequent enrichment that has affected this sample set can neither be deciphered from Sm-Nd nor Sr isotopic systematics. The Sm-Nd isotopic system was probably re-enriched during the ascent with the alkaline basalts in the Neogene but did not have enough time to re-equilibrate, or the enrichment was not high enough. It seems that some of the samples even seem to have kept the isotopic record of depletion for Neodymium.

Strontium isotopic systematics of some rare plagioclase grains indicate that they have been more strongly affected by the alkaline basalts, as they kept the corresponding isotopic signature of the alkali basalts. Whereas Strontium isotopic systematics of the clinopyroxenes are in general lower and still have values corresponding to the mantle. Recalculated  $\epsilon_{\text{Hf}}^{\text{initial}}$  values for clinopyroxenes and plagioclases differ, which is either related to the enrichment of the plagioclases by the infiltrating melts or the fact that their source of melt extraction is different.

## **Chapter 6:**

### **Combined U-Th-Pb and Hf isotope analyses of zircons from the South eastern volcanic Province (SEVP), Spain - evidence for intensive nappe stacking**

#### **6.1. Abstract**

Zircons from three localities within the South Eastern volcanic Province (SEVP) were subject for this study. The aim was to obtain an age spectra of the underlying crust by U-Pb analyses and information about how the crust developed over time by Hf isotope analyses of the same spots on the corresponding zircon grains.

U-Pb analyses of all three localities are very similar and show a very large spread in ages from the Neogene to the Archean, with major age distributions around 0.3 to 0.4 Ga, 0.5 Ga and 0.6 to 0.7 Ga, while some minor age distributions are around 1 Ga to 1.1 Ga, 1.8 Ga to 2.2 Ga, 2.4 to 2.6 Ga and 2.9 to 3 Ga. Neogene ages are prominent in all localities with ages around 2.6 Ma and some minor age distributions from 4 to 8 Ma, reflecting eruption ages of the alkali basalts and Sr-K rich melts further to the Southwest of the SEVP.

Two major trends for crustal evolution from a depleted mantle source are visible from Hf isotope analyses, with the first starting from 1.0 to 1.5 Ga from the depleted mantle and being recycled during the Caledonian and Variscan events and the second starting in the Archean and being recycled at a time around 2.1 to 1.8 Ga. Mixing of different crustal sources occurred at a time around 0.5 to 0.6 Ga.

Most zircons are probably derived from a provenance region that is related to the time of the assembly of Gondwana, with some zircons being transported from the West African Craton and the Arabian Nubian shield.

Comparison to age results from other localities within the Betic Cordillera shows that the crust is a product of intensive nappe stacking.

## 6.2. Introduction

The Betic Cordillera and in particular the South Eastern Volcanic Province, has been the subject of many geological and geochemical studies. The interest stems from the changing geotectonic situations as a result of the relative movements of the African and the Iberian plate with time and their ongoing convergence. The geotectonic situations resulted in a change of magmatism from subduction related calc-alkali magmatism to rift-related basaltic magmatism in the volcanic centers close to the village of Casas de Tallante.

The alkali basaltic eruptions at Cabezo Negro de Tallante have transported numerous (plagioclase-) spinel lherzolite xenoliths together with amphibole, plagioclase and clinopyroxene megacrysts and crustal xenoliths to the surface, which were subject for several geochemical investigations (e.g. Dupuy et al., 1986; Schaefer et al., 2000; Kogarko et al., 2001; Rampone et al., 2010; Bianchini et al., 2011). The peridotites stem from a narrow temperature- and pressure range between 900 – 1000°C and 7 – 20 kbar respectively (see chapter 5.5.1). Kogarko et al. (2001) suggested that they were part of a rising mantle diapir which was metasomatized by melts similar to the host Si-poor, Na-rich alkali basalts / basanites up to tephrites and hawaiites (Duggen et al., 2003; Duggen et al., 2005). The timing of depletion of these mantle xenoliths has been, based on a Hf model age of one sample from Cabezo Negro de Tallante, estimated to be 1.6 Ga with respect to the CHUR (Chondritic Uniform Reservoir) (Bianchini et al., 2011). From own work (see chapter 5.6), we suggest an age of depletion to be around 450 Ma, based on a Lu-Hf isochron of three samples from own work and one sample of Bianchini et al. (2011) and Beccaluva et al. (2004).

Not much is known about the crust underneath the SEVP. Crustal rocks investigated are gneisses, graphitic schists, a dacite and its Al-rich restitic enclaves of more distant regions of the Betic Cordillera near Almería (Zeck and Whitehouse, 1999; Zeck and Williams, 2001; i.e. Zeck and Williams, 2002). The age distribution of the grains in these rocks is well documented by the work of these authors. It will serve as a comparison for our work on the zircon age distribution of the volcanics from the Tallante region. Thus we compare the crust from a subduction with a rift setting. The age of the crust underneath the SEVP is completely unknown. We therefore carried out U-Pb isotope measurements on zircons from tuff layers of three localities close to the village of Casas de Tallante combined with in situ Hf isotope analyses. Information should be obtained

on crustal evolution trends (juvenile crust accretion, crust recycling, crustal mixing), as well as provenance regions.

Additionally, the question whether components of detrital origin, e.g. Gondwana derived sediments are a part of the lower crust beneath the SEVP, should be considered. Previous studies have shown that the palaeoposition of Iberia during the assembly of Gondwana plays an important role in the structural makeup of the Iberian crust (Fernandez et al., 2010).

### **6.3. Geological Setting and previous work**

The content of this chapter stems mostly from chapter 5.2 with minor modifications at the end.

Since the breakup of Gondwana, the African plate is showing a constant movement towards the north. It resulted in the convergence of the African and the Iberian plate, enclosing the Alboran microplate.

The subsequent evolution of the African-Alboran-Iberia region in the neogene is still highly disputed. Several models for the latest timespan and the reason for the change from subduction like to intraplate like magmatism in the Alboran, the northern African and southern Spanish regions have been proposed from which we will only discuss the most important ones.

Eastward directed subduction of the Tethys slab is one possible scenario as proposed by e.g. Duggen et al. (2005). They suggested that slab derived fluids and melts caused subduction like magmatism. Roll back and delamination of subcontinental lithosphere is believed to be the process responsible for a westward migration of the subduction line, the extension of the basin and upwelling of plume material, which is thought to have produced Si-poor and K-poor magmatism.

In contrast, Turner et al. (1999) suggest convective removal of lithospheric mantle beneath the Alboran basin to be the most likely process and to be responsible for extensional magmatism.

As an alternative scenario, the rising of a mantle diapir may have caused magmatism as proposed by Weijermars et al. (1985).

Intraplate like magmatism also occurred in the south eastern coastline of Iberia, the south eastern volcanic province which forms part of the Betic Cordillera.

The rocks related to the extensional phase of this African-Alboran-Iberian setting, are made up of calc-, high-K calc alkaline and shoshonitic, ultrapotassic and alkali basaltic volcanic rocks (see compilation Duggen et al., 2004).

Alkali basalts are the most recent rocks in that area and were emplaced by phreatomagmatic eruptions, forming several small volcanic centers in the SEVP. Mantle xenoliths, megacrysts and crustal xenoliths, were entrained during the ascent of the magmas and can be collected on most of the outcrops.

Cabezo Negro de Tallante is one well-known volcano that was emplaced into the Permian mica shists 2.6 to 2.8 Ma ago (K-Ar; (Bellon et al., 1983)) and is situated close the small town of Cases de Tallante in the SEVP (see Fig.5.1). A remarkable tuff layer can be found in between the basalts which has been deformed by volcanic bombs during the eruptions. The volcanic rocks contain numerous spinel and plagioclase lherzolites with specimen sizes up to 20 cm, as well as megacrysts and few crustal xenoliths.

Mantle nodules from Cabezo Negro de Tallante were subject for several studies. The major part of the peridotites are spinel or plagioclase lherzolites, with pressure and temperature ranges between 915 – 1030°C and 8 – 16 kbar respectively (Capedri et al., 1989; Beccaluva et al., 2004). Beccaluva et al. (2004) have subdivided the occurring peridotites into three groups: protogranular anhydrous spinel peridotites, amphibole/phlogopite-bearing harzburgites and orthopyroxenites with gabbro/anorthosite veinlets and amphibole/phlogopite bearing clinopyroxenites.

They often contain pyroxenite or gabbroic anorthosite veinlets which are due to their deformation and textural state not related to the alkali basalts (Dupuy et al., 1986).

Diffusion profiles in minerals of spinel lherzolites from Tallante by Kogarko et al. (2001) revealed that the peridotites ascended as a diapir with a velocity of 10 mm/a or less during a timeframe of about 3-4 Ma to a depths of 15 km in the crust before they were affected by the rising alkali basalts that themselves have been molten in the garnet stability field (Dupuy et al., 1986). Mantle diapirism is also supported by investigations of spinel-pyroxene symplectites from Tallante (Shimizu et al., 2008).

They are thought to have been affected by two types of metasomatism, with one that has an anorogenic and another one with clear subduction related characters. This can be seen from the differently enriched Sr and Nd isotopic systematics of the xenoliths (Beccaluva et al., 2004).

Strontium isotope ratios suggest that mantle xenoliths, megacrysts and the host alkali basalts have different magmatic sources.

Based on major and trace element studies, a complex history of the upper mantle underlying Tallante has been suggested (Dupuy et al., 1986) with multiple melting events and metasomatism that may have produced heterogeneous peridotite portions within very short scale distances.

Hafnium isotope studies of mantle peridotites by Bianchini et al. (2011) revealed a Hafnium model age of the most radiogenic sample of 1.6 Ga for CHUR and 1.28 Ga for the depleted mantle. No further age determinations considering the mantle underlying the SEVP are available.

The crustal framework of the deeper crust is still unknown. U-Pb investigations of zircons from a graphitic schist of the Alpine Alpujarride nappe complex (Zeck and Williams, 2001) and the xenoliths of a dacite from Cerro del Hoyazo (Zeck and Williams, 2002) revealed a wide age spectra of the crust from 320 Ma to 2.8 Ga with distinct age groups in between and a gap from 1.2 to 1.8 Ga. As both areas are located within the Betic Cordillera, these results can be regarded as being a potential reference for the makeup of the lower crust beneath Cabezo Negro de Tallante.

Samples for this study were collected from Cabezo Negro de Tallante (see Fig.5.1), a place next to the Highway close to San Isidro and Alto de las Cutandas, which are all alkali volcanic outcrops within a short scale distance of a few kilometers to each other, close to the town of Casas de Tallante.

#### **6.4. Material and Methods**

We have collected samples from three alkali basaltic outcrops within the SEVP Alto de Las Cutandas (ALCS), Cabezo Negro de Tallante (CNTS) and close to San Isidro (CG)). Samples were either taken from the tuff layers (ALCS, CNTS), which also contained mantle xenoliths or from the detritus of the disintegrated basalts (CG).

The samples were sieved in the field to grain sizes less than 1000  $\mu\text{m}$ . These layers are very soft and could therefore be sieved very easily. The tuff layers contain numerous fragments of the

crust that they erupted through and zircons extracted from there were used to reconstruct a section through the lower crust.

In a further step, samples were deposited in which great care was taken in order not to lose a population with only few tens of  $\mu\text{m}$  in diameter, potentially containing zircons. Depositing was followed by heavy liquid segregation using bromoform with a density of  $2.9 \text{ g/cm}^3$  and subsequent treatment of the heavy mineral fraction with a Frantz® magnetic separator. Amperage of the instrument was increased up to 1.6 A in several lower steps before and only grains from more than 1.6 A were considered for further preparation steps. Mineral separates were treated with 6 M ultrapure HCl for one hour on a hotplate at  $50^\circ\text{C}$  in order to remove minerals such as apatite that can easily be mistaken for zircon and sieved with mesh sizes of 50  $\mu\text{m}$  and 100  $\mu\text{m}$ . For each sample, sieve fractions with grain sizes  $< 50 \mu\text{m}$ ,  $50 - 100 \mu\text{m}$  and  $> 100 \mu\text{m}$  were acquired. Samples from all localities contained up to several thousand grains, with most grain sizes smaller than 50  $\mu\text{m}$  and only a small fraction greater than 100  $\mu\text{m}$ . Zircons were carefully pipetted or handpicked with the use of a stereomicroscope, embedded in epoxy resin and polished.

Prior to analysis, the zircon mounts were cleaned in an ultrasonic bath with ultrapure benzene and coated with gold. Cathodoluminescence images, produced with a Joel JSM-6490 and a Gatan MiniCL detector revealed internal structures and growing patterns of the single crystals which enabled us to distinguish between different growth domains within the crystals for precise measurements by laser ablation ICPMS later.

#### **6.4.1. LA-ICPMS U-Th-Pb analysis**

The descriptions of the measurement conditions in this chapter for U-Th-Pb isotopes are taken from chapter 4.4.2 and were slightly modified.

From each sieve fraction of each sample locality, zircons were mounted, polished and analyzed for U-Th-Pb isotope ratios by laser ablation ICP-MS.

Where possible, core and rim domains were analysed, using a New Wave Research® UP-213 ultraviolet laser system with a teardrop shape low-volume laser cell, for a fast washout, connected to a Thermo-Finnigan® Scientific Element 2 ICPMS with Ni X skimmer and Al

sample cones. Several hundred grains per sample were analysed, with laserspot diameters varying from 20 to 40  $\mu\text{m}$ , depending on the grainsize.

Measurements were performed, following the procedures of Gerdes and Zeh (2006; 2009). For data evaluation and as an external standard, we used standard GJ-1. Data was processed, using a self-created Excel® spreadsheet by A. Gerdes. Raw data was corrected for common lead, elemental fractionation and instrumental mass discrimination. Only concordant ages (90 – 110% concordance) were considered for further interpretation and discussion.

Prior to laser ablation analysis, gold coating was removed with ultrapure Ethanol. In order to remove any common lead from the surface that could stem from the preparation process, zircon mounts were cleaned with 2 % ultraclean nitric acid for 30s.

Spot sizes for all analyses varied from 20  $\mu\text{m}$  to 33  $\mu\text{m}$  and the fluence was around 4-6  $\text{J cm}^2$ . Laser holes were drilled with penetration depths of about 20  $\mu\text{m}$ . A detailed description of the analytical procedures used here for U-Pb dating is described in Gerdes and Zeh (2006; 2009). For internal standardization, we used as primary standard GJ-1 zircon (Jackson et al., 2004).

The Plešovice zircon standard (Slama et al., 2008) is routinely measured in the laboratory of the GUF and yields a concordant age of  $338 \pm 2$  Ma, which is in perfect agreement to data published by Slama et al. (2008) from other laboratories.

Measurements were performed in several sessions, with offset values for  $^{238}\text{U}/^{206}\text{Pb}$  for the major part of the sessions being in the range between 1 to 15 % and for one day with a value around 50% compared to the reference values for GJ-1.

Usually the U-Pb data was corrected for common Pb using the measured Hg-interference corrected  $^{204}\text{Pb}$  signal and a Stacey and Kramers (1975) composition. However, for many analyses the  $^{204}\text{Pb}$  was below detection limit. Age probability-density plots were created using the Excel® spreadsheet of Sircombe (Sircombe, 2004). Concordia diagrams were created using Isoplot 3.7 (Ludwig, 2008). Some of the data points as listed in Table A.6.1, were saturated in the signal for  $^{238}\text{U}$  due to the usage of the counting mode, plotting above the concordia line. These points were not considered for the concordia diagrams.

## 6.4.2. LA-MC-ICPMS Hafnium analysis

The following descriptions of the Hf isotope measurements are taken from chapter 4.4.3 with minor modifications.

Hafnium isotope measurements were performed with a Thermo-Finnigan Neptune multicollector (MC)-ICPMS at GUF coupled to New Wave UP213 NdYAG laser, following the procedures described in Gerdes and Zeh (2006; 2009). Laser spots with diameter 40  $\mu\text{m}$  were drilled with repetition rate of 5.5 Hz and an energy density of 6  $\text{J}/\text{cm}^2$  during 55 s of data acquisition. The 40  $\mu\text{m}$  Hf analysis spot was set on top or just next to the U-Th-Pb spot in the same growth domain as indicated by CL images. Penetration depths of the laser spots are in the range of about 40 to 50  $\mu\text{m}$ .

Data were processed by the adjustment of all analyses to a  $^{176}\text{Hf}/^{177}\text{Hf}$  isotope ratio of 0.282160 of reference standard JMC475. GJ-1 and Plešovice standards were measured during every measurement session to ensure high Accuracy and reproducibility. Average  $^{176}\text{Hf}/^{177}\text{Hf}$  isotope ratios of GJ-1 in 7 analyses were at  $0.282025 \pm 0.00002$  (2 sigma), which is in accordance to published reference values (Gerdes and Zeh, 2006).

$\epsilon\text{Hf}(t)_{\text{initial}}$  values were calculated from the measured  $^{176}\text{Hf}/^{177}\text{Hf}$  and  $^{176}\text{Lu}/^{177}\text{Hf}$  ratios, using the corresponding age as obtained before by the U-Th-Pb analyses and the CHUR values for  $^{176}\text{Lu}/^{177}\text{Hf}$  and  $^{176}\text{Hf}/^{177}\text{Hf}$  of 0.0336 and 0.282785 (Bouvier et al., 2008) and a decay constant of  $1.867 \cdot 10^{-11}$  (average Scherer et al., 2001; Söderlund et al., 2004). Only datapoints with concordant ages (90 – 110% concordance) and small errors were considered for further interpretations. Data in table A.4.2 without U-Pb ages did not have a concordant age.

## 6.5. Results

### 6.5.1. Zircon morphology

Grainsizes < 50  $\mu\text{m}$  and between 50 to 100  $\mu\text{m}$  are most abundant; only a minor fraction of the zircons in each sample is larger than 100  $\mu\text{m}$ .

Most of the zircons from grain sizes  $< 50 \mu\text{m}$  and  $50 - 100 \mu\text{m}$  have oscillatory zoning, are monophase and colourless or reddish. They are subrounded to rounded, and seem to be detrital. Strong variations in the U contents of the grains can be seen in the cathodoluminescence images by different levels of brightness. This was confirmed by the obtained uranium contents ranging from  $< 100 \text{ ppm}$  up to  $> 700 \text{ ppm}$ .

A remarkable feature of some of the small sized zircons is a thin, illuminating rim with diameters of around  $10 \mu\text{m}$ .

Zircons  $> 100 \mu\text{m}$  are mostly subeuhedral with partly rounded edges and show indications of a magmatic origin while a few of them show multi-phase growth (Fig.6.1).

Fig.6.1: Cathodoluminescence images of subeuhedral zircon grains  $> 100 \mu\text{m}$  from Cabezo Negro de Tallante. Yellow circles indicate positions for the laser spots used for the determination of the U-Pb ages and Hf isotopic composition. U-Pb ages are around 2.6 Ma, corresponding to the age of eruption of the alkali basalts.

### 6.5.2. U-Pb age determinations

Results are listed in Table A.6.1. Only ages with concordance levels of 90 to 110 % for  $^{206}\text{U}/^{238}\text{Pb}$  and  $^{207}\text{Pb}/^{206}\text{Pb}$  were considered in the following interpretation (Fig.6.2, 6.3).

For the sample from Alto de las Cutandas (ALCS-1), only 24 out of 67 ages from the timespan > 100 Ma are clearly concordant. Thirty five zircons have ages younger than 5 Ma with a major age peak around 2.6 Ma. For such young zircons,  $^{204}\text{Pb}$  and  $^{207}\text{Pb}$  cannot be analyzed precise enough so that  $^{207}\text{Pb}/^{206}\text{Pb}$  ages cannot be determined and there is no obvious concordance. However, in most cases, we see good correlations of  $^{207}\text{U}/^{235}\text{Th}$  with  $^{206}\text{U}/^{238}\text{Pb}$  and therefore consider these young ages to be real. Older ages peak around 0.3, 0.5 – 0.6, 0.8, 1.0, 1.4, 1.6, 1.8 – 2.2, 2.4 and 2.8 Ga.

86 out of 151 zircons from San Isidro (CG-Z1 – CG-Z3) with ages more than 100 Ma give concordant results, whereas a minor part of 32 zircons with ages is less than 10 Ma. Most ages range from around 0.3 to around 3 Ga with a major age peak at around 600 Ma. Minor age distributions are around 0.3, 0.7, 1.0, 1.2, 1.8 – 2.2, 2.4 – 2.6 and 2.9 – 3.0 Ga. Ages less than 10 Ma are mostly between 2 to 3 Ma and around 4.2, 5.5 and 6.5 Ma.

Nearly half of the zircons (62 out of 119) from Cabezo Negro de Tallante CNTS-1 are concordant with additionally 25 grains that are less than 10 Ma old. Zircons with ages older than 100 Ma have main age peaks around 0.3, 0.5 to 0.8, 1.0, 1.8 to 2.1 and 2.4 Ga. Young zircons peak around 2 to 3, 4, 6 to 7 and 7 to 8 Ma.

Fig.6.2 : Concordia diagram of all analyses > 100 Ma for all three localities.

All three sample localities give completely overlapping age spectra including the one from the weathered matrix of the basalts (CG-Z1 – CG-Z3). As a characteristic feature, all three sample localities show a wide range of ages from the Neogene up to the Archean. Major age clusters are around 300 to 400 Ma, 500 to 700 Ma, 1 Ga to 1.1 Ga, 1.8 Ga to 2.2 Ga, 2.4 to 2.6 Ga and 2.9 to 3 Ga. Oldest ages are achieved by samples from Alto de las Cutandas and San Isidro, whereas ages for Cabezo Negro de Tallante reach only up to 2.4 to 2.5 Ga.

The highest percentages of concordant ages for all localities are achieved for analyses from 300 to 400 Ma and 600 to 700 Ma.

For all sample localities, there is a remarkable gap of ages between 1.1 and 1.8 Ga, which can clearest be seen in the age spectra of CNTS-1.

Zircons younger than 10 Ma can be found in all samples. They generally occur in the fraction with grain sizes larger than 100  $\mu\text{m}$ . A major age peaks is around 2.6 Ma, the age of the volcanic activity in Tallante. Minor age peaks are between 4 and 5 Ma and 7 and 8 Ma, the ages of the Ca-alkaline volcanism, a few tens of kilometers further west and around 150 kilometers further to the SW (Turner et al., 1999; Duggen et al., 2004).

No analysis of the thin illuminating rim around most zircons was possible, because its average diameter smaller than the laserspots used.

Fig.6.3: U-Pb based age distribution pattern of Alto de las Cutandas (ALCS; A-B), Cabezo Negro de Tallante (CNTS; C-D) and San Isidro (CG; E-F) with corresponding age pattern of zircons younger than 10 Ma inserted in each figure.

### 6.5.3. Initial Hafnium isotopic compositions

The Hf isotope compositions are reported in the  $\epsilon\text{Hf}(t)$  notation. In general,  $^{176}\text{Lu}/^{177}\text{Hf}$  isotope ratios are below 0.002, which is expected as Lu has only very low abundances in zircon crystals (Patchett et al., 1981). Therefore, the correction of  $^{176}\text{Hf}/^{177}\text{Hf}$  isotope ratios for radiogenic  $^{176}\text{Hf}$  does only have a minor effect on the isotope ratio.  $\epsilon\text{Hf}(t)$  of all samples are below the evolution line for the depleted mantle for the corresponding age with values ranging from -25.3 to 8.8  $\epsilon\text{Hf}(t)$ , while the major part is in the range between -9 and +8. The combination of the  $\epsilon\text{Hf}(t)$  with their corresponding U-Pb ages shows one vertical trend from  $\epsilon\text{Hf}(t)$  around 10 down to -15  $\epsilon\text{Hf}(t)$  units and two diagonal trends with  $\epsilon\text{Hf}(t)$  values becoming less the younger the ages are.

Fig.6.4: Hf evolution diagram for Cabezo Negro de Tallante (green) and additional data from the West African Craton (black squares; (Abati et al., 2012).  $\epsilon\text{Hf}(t)$  values were plotted against their corresponding U-Pb ages. Crustal evolution trends are shown in blue and red, with an assumed  $^{176}\text{Lu}/^{177}\text{Hf}$  isotope ratio of 0.0113 (Rudnick and Gao, 2003). The red circle surrounds ages younger than 10 Ma with  $\epsilon\text{Hf}(t)$  values close to the chondritic value. For a more detailed illustration of these young ages, see Fig.6.7.

One group of samples with ages below 10 Ma, results in a very narrow  $\epsilon\text{Hf}(t)$  range of around 2 to 5 (Fig 4.6). Three age groups can be distinguished with one at around 2 to 3 Ma, followed by a group from 4 to 5 Ma and another one at around 8 Ma.  $\epsilon\text{Hf}(t)$  values of all groups are nearly

constant with some ages being slightly higher or lower than the average that is around 3 to 4  $\epsilon\text{Hf}(t)$  units.

By plotting these values into a Hf evolution diagram, crustal evolution trends, starting from the depleted mantle can be projected and compared to the sample set (Fig.6.4). A  $^{176}\text{Lu}/^{177}\text{Hf}$  of 0.0113 was chosen for the calculation of crustal evolution trends (Rudnick and Gao, 2003).

## **6.6. Discussion**

### **6.6.1. Origin of the Zircons**

Zircons were collected from the tuffs and the weathered matrix of the volcanic edifices (see above). They should be the debris of the metamorphic crustal xenoliths which are included in the volcanics but it cannot be excluded that there is also debris from the immediately underlying Permian mica schists included. As the results of zircon analyses from the restitic enclaves of a dacite in Cerro del Hoyazo by Zeck and Williams (2002) match in most points the age distribution pattern of this study, it can be said that we either did not have a recent addition of zircons close to the tuff layers or that if there was an addition of zircons, they have a similar age spectra like the crust beneath Cabezo Negro de Tallante.

The wide range of ages from Neogene to Archean implies that some of the zircons analyzed could have been transported from a more distant region to the SEVP as no Proterozoic or Archean rocks are reported from the Betic cordillera. Previous studies have shown that, zircons are able to survive long distance transports without being destroyed (Morag et al., 2011). During the assembly of Gondwana, zircons that are Archean in age could have been transported from the West African craton onto the Iberian plate before the breakup of Gondwana (Fernandez et al., 2010).

### **6.6.2. Age distribution and crustal evolution**

So far, no data about the geochronological makeup of the crust beneath the Tallante region exists, so that we do not have any direct database to compare our geochronological records with. However, age information is available on the crustal make beneath Cerro del Hoyazo, which is

located around 150 km to the southwest of Cabezo Negro de Tallante (Zeck and Williams, 2002) and the crust from the Alpujarride graphitic schist, close to Cerro del Hoyazo (Zeck and Whitehouse, 1999), which is about the same age as the mica schists around Cabezo Negro de Tallante. These regions are all located within the Betic Cordillera, which assumes that both areas could have a similar history in age.

Fig.6.5: Compilation of U-Pb ages of all three localities from the SEVP, with ages from 0.1 to around 3 Ga (A) and Neogene ages of around 2 to 11 Ma (B).

Fig.6.6: Comparison of the age distributions of the SEVP (A) to the results of the Alpujarride graphitic schist (Zeck and Williams, 2001) (B), the xenoliths of the dacite of Cerro del Hoyazo (Zeck and Williams, 2002) (C), a middle Cambrian quartz-rich sandstone in Morocco (Avigad et al., 2012) (D) and a middle Cambrian quartzite in SW Sardinia (Avigad et al., 2012) (E).

Additionally, detrital zircons from Morocco and Sardinia can be taken as a reference for this study (Avigad et al., 2012) as they were connected with each other during the assembly of Gondwana.

The age distribution patterns of all three localities analyzed in this study are very similar (Fig.6.3). Differences are expressed in the maximum age of crystallization that is the highest for San Isidro or the occurrence of few ages in the timespan between 1.0 and 1.8 Ga. These differences are not significant though and can partly be explained by the number of concordant ages for each locality. San Isidro has the oldest U-Pb ages but is also the locality with the most data available.

The age distribution patterns between the three localities around Casas de Tallante and Cerro del Hoyazo have nearly the same range in ages, starting from around 300 Ma up to 2.8 Ga. Major age peaks of the dacite xenoliths comprise 320 to 350 Ma, 650 to 550 Ma, 0.9 to 1.1 Ga, 1.9 to 2.1 Ga and 2.5 to 2.8 Ga. These results are in good agreement to our results as described earlier. As a difference, no data older than 2.9 Ga is existent in their dataset (Zeck and Williams, 2002), which points to a slightly different stratigraphic unit. From the coincidence of the age distribution between the two localities we conclude that the zircons for Tallante are derived directly from the disintegrated crustal xenoliths there.

The age spectrum of the Alpujarride graphitic schist (Zeck and Williams, 2001) has the highest peak at around 0.6 to 0.7 Ga and some minor peaks around 0.3 to 0.4, 0.9, 1.1, 1.4 and 1.9 to 2.2 Ga. This is mostly in accordance to our own results of the SEVP with the difference that no ages older than 2.2 Ga are present in the age spectrum of the graphitic schist. Because of a similar age of this schist and the mica schists, surrounding the alkali basalts in the SEVP, we take its age spectra as a representative of the mica schists. By doing so, it can be seen that most ages from our samples match the ages of the surrounding country rocks. The absence of ages older than 2.2 Ga can probably be related to a smaller number of analyses (statistical effect).

Age spectra of Morocco and SW Sardinia (Avigad et al., 2012) are nearly the same with major age peaks around 0.6 to 0.8 Ga and minor age distributions around 0.9 to 1.0, 1.6, 1.8 to 2.2 and 2.4 to 2.7 Ga. Compared to the results of the SEVP, there is no evidence for the Variscan

orogeny in the Moroccan and Sardinian zircons, as ages around 0.3 Ga are completely missing, which was expected as the sediments are Cambrian.

Age spectras of the Alpujarride graphitic schist and the xenoliths within the dacite are very similar, which can be interpreted as as a stacking of nappes within the Betic cordillera. This stacking can also be observed for the SEVP, as the age spectra of these samples is very similar to those of Cerro del Hoyazo, with the mica schists being equivalent to the graphitic schist, while some older ages might point to a slightly different stratigraphic unit or may be a statistical effect.

In general, the comparison to these four other localities show very similar age spectra, pointing towards a Gondwanan source of detrital zircons.

More information on crustal evolution and crustal reworking can be obtained from the Hf isotopes of the zircons and the comparison with the mantle evolution line (Fig 6.4). We only analyzed the zircons from Cabezo Negro de Tallante as representative for the whole volcanic field. Two major crust building phases, probably starting from a depleted mantle source, show an obvious trend.

It appears from the projection of the Hf-isotopes onto the depleted mantle that the same primary crustal source rocks with ages between 1 to 1.5 Ga have been reworked during the assembly of Rodinia, the Caledonian orogeny and the Variscan orogeny. No crustal rocks from Iberia fall into that age range of 1 to 1.5 Ga, which means that the zircons, derived from a depleted mantle around that time must stem from somewhere else than Iberia.

In addition, the timespan between 500 and 600 Ma shows a distinct vertical array of  $\epsilon\text{Hf}(t)$ . During this time span, further crustal components with widely different primary ages seem to have been reworked, mixed and homogenized, resulting in this remarkable trend that goes down to around -14  $\epsilon\text{Hf}$  units.

Ages between 1.0 and 1.8 Ga are very scarce in all localities, which is typical for a Gondwanan to Peri Gondwanan provenance (Zeh and Gerdes, 2010) like the SEVP.

Ages between 1.8 and 2.5 are more common again followed intermittently by few ages up to 3 Ga. The projection back to the depleted mantle evolution line of the late Proterozoic to Proterozoic zircons from Cabezo Negro de Tallante indicates the formation of juvenile crust sometime in the late Archean (Fig.6.4). The existence of such old zircon grains and their

morphological features, with special regard to their size and their roundness, implies that these zircons are detrital and do not have a direct magmatic origin from within the Betic Cordillera.

Looking back in the Earth's history, it can be seen that before the breakup of Gondwana, the Iberian Plate was attached to the West African Craton (Avigad et al., 2012). By comparison of the U-Pb age spectra of this study with age distributions of zircons from Cambrian sandstones of Morocco and Sardinia (Avigad et al., 2012), we can see a good agreement with the older ages (Fig.6.6). A geochronological study of zircons from the Anti-Atlas mountains, a part of the West African Craton, is also in good agreement with the Palaeoproterozoic and Archean ages and the Caledonian crustal mixing trend (Abati et al., 2012). It also shows that most of the zircons of the SEVP could stem from the West African Craton and have been recycled and mixed in Caledonian and Variscan times. It implies that detrital zircons have been transported in Gondwanan times to the Iberian Plate, which were then in a later period (e.g. Variscian) metamorphosed and are now a part of the crust of the Betic Cordillera.

Rocks with U-Pb ages around 1 Ga, were found in the Arabian Nubian Shield and are probably another provenance region for the SEVP (Be'eri-Shlevin et al., 2012). These zircons were reworked and recycled during the Caledonian and variscian orogeny.

Our new U-Pb results and the Hf isotope data for Cabezo Negro de Tallante and the comparison to areas nearby (Zeck and Williams, 2001; Zeck and Williams, 2002) and the age signature of the West African Craton, implies that it is made up of zircons from the West African Craton that were transported during the time of the assemblage of the Gondwana terranes onto the Iberian plate and were reworked during the Caledonian and Variscan Orogeny. During the Alpine orogeny, the Betic cordillera was formed and caused a stacking of nappes. The samples collected in this study showed the characteristics of this part of the crust but did not allow a characterisation of the basement underneath it.

### **6.6.3. Magmatic zircons younger than 10 Ma**

The sample set of each locality around Casas de Tallante contains small amounts of zircons > 100  $\mu\text{m}$  with subeuhedral shapes that are slightly only rounded on the edges (Fig.6.1). These

zircons have shown to be Neogene in age, with a large fraction that is 2 to 3 Ma and minor age distributions around 4, 5 – 6, 7 – 8 and 11 Ma.

Zircons that are of magmatic origin have been described to be euhedral in shape and to be larger in grain size (Hollis and Sutherland, 1985). The zircons described above match the morphological criterias for magmatic zircons and are in good agreement with their corresponding U-Pb ages (which are in good agreement to the U-Th ages) to the K-Ar ages of the Tallante basalts of Bellon et al. (1983). The roundness can be explained as being the result of interaction of the zircons grains with the basaltic melts. Therefore it cannot be excluded that these zircons are cogenetic with the basalts and record the time of eruption.

Fig.6.7:  $\epsilon\text{Hf}(t)$  distribution of zircons from Cabezo Negro de Tallante with ages < 10 Ma. Values scatter from around 2 to 5  $\epsilon\text{Hf}$  units according to a slightly depleted mantle source.

In that case, the Hf isotopes provide information on the mantle source of the basanites. The  $\epsilon\text{Hf}$  values range between +2 and +5  $\epsilon\text{Hf}(t)$  (Fig.6.7) for all three age groups as discussed earlier. These characteristics indicate that these zircons could be derived from a depleted mantle source that has been recycled later or that the source of melt extraction is a slightly depleted to a primitive mantle source. An origin from the depleted mantle is though unlikely as we do not find any evidence for zircons that are on the same line for a crustal evolution and the fact that these zircons all show, within a certain range, similar  $\epsilon\text{Hf}(t)$  values. It is therefore very likely that the basaltic rocks were extracted from slightly depleted to primitive mantle source and that there is no cogenetic relationship towards the rest of the zircon population analyzed for this locality. These findings are in accordance to the results of a study of Cebria et al. (2009). They propose a

model in which the alkali basalts are derived from a primitive mantle source that has experienced minor interaction with metasomatized lithospheric mantle melts. Similar young ages (around 6 Ma), were obtained from euhedral zircons in a dacite (Zeck and Williams, 2002) and are thought to represent the age of eruption of the corresponding area.

Ages from around 6 to 8 Ma could be related to the extrusion of Ca-alkaline melts in the Miocene, further to the West and Southwest of Cabezo Negro de Tallante (Turner et al., 1999; Duggen et al., 2004).

## **6.7. Conclusions**

This study was set out to clarify the question of how the lower crust beneath the SEVP is built up in terms of the geochronological record and the origin of melt extraction, to be clarified by U-Pb and Hf isotope analyses. The extensive study of crustal zircons, collected from the Tuff layers of Cabezo Negro de Tallante, Alto de Las Cutandas and San Isidro, all located in the SEVP, has shown a wide age range from the Neogene up to the Archean. All three localities show almost the same age patterns. The comparison of the ages from all three localities and Hf isotope systematics from Cabezo Negro de Tallante to crustal age distributions and Hf isotope systematics from selected other localities allowed us to get a better view in the understanding of the crust beneath the SEVP.

Before the breakup of Gondwana, the Iberian plate was in direct connection to the West African craton from which zircons have probably been transported onto the Iberian plate. These zircons have late Proterozoic ages which were mixed and reworked during the Caledonian orogeny. Hf isotope data from Cabezo Negro de Tallante suggests that juvenile crust formation occurred around 1 to 1.5 Ga, whereas no rocks of this age are known in the Betics. These zircons are probably also Gondwana derived from a locality, situated in the Arabian Nubian Shield (Be'eri-Shlevin et al., 2012). They were recycled during the Caledonian and the Variscan orogeny, creating the younger array of crustal development. A vertical trend around 0.6 Ga, shows that zircons with different Hf isotopic compositions have interacted, forming a crustal mixing trend at the time of the Caledonian orogeny.

A minor part of the zircon population of all three localities is related to the magmatism that brought up the mantle xenoliths to the surface and formed the alkali basaltic hills in the SEVP. They are subeuhedral in shape and are in general bigger in their grain size than the rest of the zircon population with diameters greater than 100  $\mu\text{m}$ . Their initial  $^{176}\text{Hf}/^{177}\text{Hf}$  isotopic signatures are, if correlated to their U-Pb age, corresponding to a slightly depleted mantle source. The major part of these zircons have ages around 2.6 Ma, which is in good agreement to K-Ar geochronological data for the alkali basalts as published by Bellon et al. (1983). A minor part yields ages from 6 to 8 Ma, which corresponds to the age of the calc alkaline melts that can be found around further Southwest of Cabezo Negro de Tallante (Turner et al., 1999; Duggen et al., 2004).

Our new data, in comparison to data from the West African Craton and more localities within the Betic cordillera shows that the lower crust beneath the SEVP records extensive recycling and crustal mixing of detrital zircons that were transported from the West African craton during the assemblage of Gondwana onto the Iberian Plate. The lower and the upper crust are a product of intensive nappe stacking during major tectonic events.

## **6.8. Acknowledgements**

We are grateful to J. Heliosch for the preparation of the zircon mounts and A. Zeh for helpful discussions.

This project has been supported by the DFG (Deutsche Forschungsgemeinschaft), project grant 1012/37-1.

## Acknowledgements

First of all I would like to express my gratitude to my supervisor Gerhard Brey for choosing me to work on this interesting and challenging project. Thank you for allowing me to go to so many international conferences to present my data and to meet highly recognized scientists from all over the world. Thank you for providing a sample set that looked so inconspicuous first but turned out to contain so many interesting results! You always managed to encourage me when I was unsatisfied!

Axel Gerdes for being a great advisor in the laboratory! You introduced me into the fascinating world of mass spectrometry and isotope geochemistry and awoke my own passion for trace element and isotope analytics. Thank you for taking so much time to help me when I experienced problems in the lab and for the numerous hours we spent talking about the evaluation and interpretation of my results.

Heidi Höfer for teaching me how to use the electron microprobe, the SEM and various preparation instruments. Your teachings allowed me to be able to work with the instruments beyond the knowledge of a regular user.

Marina Lazarov for teaching me how to do isotope dilution measurements and for the nice time we had while sharing an office.

Armin Zeh for help with the evaluation of zircon data and a lot of fruitful discussions.

Alexander Schmidt for teaching me how to use the SelFrag instrument.

Sonja Aulbach for helpful discussions about Re-Os isotope geochemistry.

Michael Seitz for help in the mass spectrometer lab.

Jan Heliosch for the preparation of my sample mounts.

Martin Okrusch for providing crustal xenoliths samples from Namibia.

Anna Neumann and Janina Schastock for their support in the clean lab.

Mandy Krebs for help during the preparation process.

Margaret Hanrahan-Denk for careful proofreading.

All other colleagues at the institute of Mineralogy for having a good time, lots of good food and a nice working environment.

I am grateful for constant support by my family, Hans-Werner, Ursula and Kathrin Luchs.

I would like to express my heartfelt gratitude to Nadin Graf. Thank you for your throughout support and your understanding during my work. You helped me to keep up my motivation!

# TIMO LUCHS

## PERSONAL DATA

- Date and place of birth: 30.04.1984, Paderborn, Germany
- Nationality: German

## EDUCATION

---

Since 01.11.2008	Ph.D. studies at Goethe University, Frankfurt am Main, Petrology and Geochemistry <b>Thesis:</b> Coupling of geological processes in the Earth's crust and mantle <b>Supervisor:</b> Prof. Dr. Brey	Frankfurt a.M.
Summer Term 2008	Graduation of Geology Studies: Diplom Geologe (Dipl.Geol.) (equal to MSc.) <b>Thesis:</b> Optimierung des Langzeitverhaltens von Hohlfasermembranmodulen zur Sanierung von kontaminierten Grundwässern <b>Supervisors:</b> Prof. Dr. Schüth (thesis) Apl. Prof. Dr. Schleyer (thesis) Prof. Dr. Brey (geological mapping) Prof. Dr. Zulauf (geological mapping)	Frankfurt a.M.
Summer Term 2005	Intermediate Diploma at Johann-Wolfgang Goethe University (equal to BSc.)	Frankfurt a.M.
Since 1.10.2003	Study of Geology/Palaeontology at Johann-Wolfgang Goethe University	Frankfurt a.M.
1996 – 2003	Kaiserin-Friedrich-Gymnasium (grammar school) Degree: Abitur	Bad Homburg
1994 – 1996	Wilhelm-Hausenstein-Gymnasium (grammar school)	Durmersheim
1991 – 1994	Primary school	Durmersheim
1990 – 1991	Primary school	Karlsruhe

## LANGUAGE SKILLS

---

- German (native)
- English (fluent)

- French (intermediate)
- Spanish (basic knowledge equal to classification A2.1)
- additionally: stays in South Africa and Spain

## EMPLOYMENT HISTORY

---

Since November 2008

**Institute for Mineralogy Dept. Petrology & Geochemistry, Frankfurt a.M.:**

- [Http://www.mineralogie.uni-frankfurt.de/petrologie-geochemie/](http://www.mineralogie.uni-frankfurt.de/petrologie-geochemie/)
- Ph.D. candidate (supervisors: Prof. Dr. Brey and Dr. Gerdes)
- Trace element and isotope geochemistry
- Geochronology and characterization of crustal (U-Pb, Hf) and mantle material (Lu-Hf, Rb-Sr, Sm-Nd) using LA-ICPMS and MC-ICPMS

End of July 2006 – end of October 2006:

**Kym L. Morton Consulting Services (KLMCS), Lanseria, South Africa (internship):**

- [Http://www.klmcs.co.za](http://www.klmcs.co.za)
- Writing of reports about the hydrogeochemistry of different diamond mines in Botswana for the identification of ground water flow paths including a one week stay at one of the mines
- Drill core logging
- Interpretation of aerial photographs
- Water table measurements
- Ground water sampling

August 2005 – Oktober 2008:

**Institute for Mineralogy Dept. Petrology & Geochemistry, Frankfurt a.M.:**

- [Http://www.mineralogie.uni-frankfurt.de/petrologie-geochemie/](http://www.mineralogie.uni-frankfurt.de/petrologie-geochemie/)
- Student assistant, main area of responsibility: Electron Probe Micro Analysis (EPMA)
- Tasks on mass spectrometer and scanning electron microscope (SEM)
- Miscellaneous duties

October 2004 – July 2005

**Senckenberg Museum, Frankfurt a.M.:**

- [Http://www.senckenberg.de](http://www.senckenberg.de)
- Temporary job superintendence

## MEMBERSHIPS

---

- Deutsche Mineralogische Gesellschaft (DMG)
- Geologische Vereinigung (GV)
- Geochemical Society (GS)

## LIST OF LITERATURE

## Scientific publications (Peer review):

- Luchs, T., Brey, G.P., Gerdes, A., Hofer, H.E. (submitted). The lithospheric mantle underneath the Gibeon Kimberlite field (Namibia): a mix of old and young components – evidence from Lu-Hf and Sm-Nd isotope systematics. *Precambrian Research*.

## Conference abstracts:

- Luchs, T., Brey, G., Gerdes, A., Hofer, H.E. (2012). Lu-Hf and Sm-Nd geochronology and geothermobarometry of the lithospheric mantle beneath the Gibeon kimberlite field, Namibia, 10IKC 6. – 11.2., Bangalore India. (Poster presentation)
- Luchs, T., Brey, G., Gerdes, A. (2011). Chronological and thermal history of the lithospheric mantle underneath the Gibeon kimberlite field, Namibia, Goldschmidt Conference 14. – 19.8, Prague Czech Republic. (Oral presentation)
- Luchs, T., G. Brey and A. Gerdes (2010). Insights on the evolution of the lithospheric mantle underneath the Gibeon Kimberlite field, Namibia. *Geochimica Et Cosmochimica Acta* 74(12): A639-A639. Goldschmidt Conference 13. – 18.6., Knoxville USA. (Poster presentation)
- Luchs, T., Gerdes, A., Brey, G. (2009). U-Pb geochronology of zircons from the South Eastern volcanic Province (SEVP), Spain, DMG Conference, 13. – 16.9, Halle. (Poster presentation)

## Upcoming:

- Luchs, T., Brey, G., Gerdes, A. (2012). Archean crust components within the Rehoboth Terrane, Namibia: evidence from xenolith derived zircons in kimberlites and carbonatites, 1st European Mineralogical Conference 2. – 6.9., Frankfurt Germany. (Poster presentation)
