# On the composition of ammonia-sulfuric acid clusters

S. Schobesberger et al.

Printer-friendly Version

The formation of particles from precursor vapors is an important source of atmospheric aerosol. Research at the Cosmics Leaving OUtdoor Droplets (CLOUD) facility at CERN tries to elucidate which vapors are responsible for this new particle formation, and how in detail it proceeds. Initial measurement campaigns at the CLOUD stainless-steel aerosol chamber focused on investigating particle formation from ammonia (NH<sub>3</sub>) and sulfuric acid (H<sub>2</sub>SO<sub>4</sub>). Experiments were conducted in the presence of water, ozone and sulfur dioxide. Contaminant trace gases were suppressed at the technological limit. For this study, we mapped out the compositions of small NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> clusters over a wide range of atmospherically relevant environmental conditions. We covered  $[NH_3]$  in the range from <2 to 1400 pptv,  $[H_2SO_4]$  from  $3.3 \times 10^6$  to  $1.4 \times 10^9$  cm<sup>-3</sup>, and a temperature range from -25 to +20 °C. Negatively and positively charged clusters were directly measured by an atmospheric pressure interface time-of-flight (APi-TOF) mass spectrometer, as they initially formed from gas-phase NH<sub>3</sub> and H<sub>2</sub>SO<sub>4</sub>, and then grew to larger clusters containing more than 50 molecules of NH<sub>3</sub> and H<sub>2</sub>SO<sub>4</sub>, corresponding to mobility-equivalent diameters greater than 2 nm. Water molecules evaporate from these clusters during sampling and are not observed. We found that the composition of the NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> clusters is primarily determined by the ratio of gas-phase concentrations [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>], as well as by temperature. Pure binary H<sub>2</sub>O-H<sub>2</sub>SO<sub>4</sub> clusters (observed as clusters of only  $H_2SO_4$ ) only form at  $[NH_3]/[H_2SO_4] < 0.1$  to 1. For larger values of [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>], the composition of NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> clusters was charACPD

Interactive Discussion

substantiate previous evidence for acid-base reactions being the essential mechanism behind the formation of these clusters under atmospheric conditions and up to sizes of at least 2 nm. Our results also suggest that yet unobservable electrically neutral NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> clusters grow by generally the same mechanism as ionic clusters, particularly for  $[NH_3]/[H_2SO_4] > 10$ . We expect that  $NH_3-H_2SO_4$  clusters form and grow also mostly by  $\Delta m/\Delta n > 1$  in the atmosphere's boundary layer, as  $[NH_3]/[H_2SO_4]$  is mostly larger than 10. We compared our results from CLOUD with APi-TOF measurements of NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> anion clusters during new particle formation in the Finnish boreal forest. However, the exact role of NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> clusters in boundary layer particle formation remains to be resolved.

#### Introduction

Atmospheric aerosol particles influence the Earth's radiation balance via aerosolradiation and aerosol-cloud interactions, the latter effect being one of the largest sources of uncertainty in predicting the current and future climate change (IPCC, 2013). An important source of atmospheric aerosol particles is the formation of molecular clusters from gas-phase precursors (vapors) and their subsequent growth to larger sizes by vapor condensation and other processes. Such new particle formation gives a potentially large contribution to regional and even global cloud condensation nuclei (CCN) populations (Merikanto et al., 2009; Kerminen et al., 2012; Lee et al., 2013), thereby affecting aerosol-cloud interactions and ultimately climate (Kazil et al., 2010; Makkonen et al., 2012; Ghan et al., 2013). However, the very first steps of the atmospheric new particle formation process are still poorly understood and subject of ongoing research (Kulmala et al., 2014). An important task in this respect is to find out the factors and underlying mechanisms that determine the initial formation of molecular clusters and particles <2 nm from vapors, and how this process varies throughout the atmosphere.

It is still largely unknown which vapors participate in atmospheric new-particle formation. The only compound that certainly plays a major role is sulfuric acid (H<sub>2</sub>SO<sub>4</sub>)

Interactive Discussion

(Weber et al., 1996; Kulmala et al., 2004b, 2006; Riipinen et al., 2007). Together with practically omnipresent water vapor (H2O), H2SO4 is believed to be the main source of new particles in the middle and upper troposphere (Lovejoy et al., 2004). However, most measurements of new-particle formation have been made close to the ground, and these particle formation events have been observed to be confined into the lower tropospheric boundary layer (Kulmala et al., 2004b; Kulmala and Kerminen, 2008; O'Dowd et al., 2009; Schobesberger et al., 2013b). Within this relatively warm boundary layer, H<sub>2</sub>SO<sub>4</sub> alone cannot explain either the particle formation or subsequent growth rate, because H<sub>2</sub>SO<sub>4</sub> concentrations are too low, typically below one part per trillion by volume (<1 pptv, corresponding to 2.5 × 10<sup>7</sup> molecules cm<sup>-3</sup>) (Kirkbv et al., 2011). Other compounds are believed to participate in the process of new particle formation by stabilizing H<sub>2</sub>SO<sub>4</sub> molecules during the formation of initial clusters (e.g., Petäjä et al., 2011; Sipilä et al., 2010). The candidate compounds for facilitating such stabilization are ions (Lovejoy et al., 2004; Kirkby et al., 2011), bases such as ammonia (NH<sub>3</sub>) (Coffman and Hegg, 1995; Ortega et al., 2008; Kirkby et al., 2011) and amines (Kurtén et al., 2008; Paasonen et al., 2012; Almeida et al., 2013), and a possibly wide range of oxygenated organic molecules (Kulmala et al., 1998; Zhang et al., 2004; Metzger et al., 2010; Schobesberger et al., 2013a; Ehn et al., 2014; Riccobono et al., 2014).

Ammonia (NH<sub>3</sub>) and its stabilizing effect on the H<sub>2</sub>SO<sub>4</sub>-H<sub>2</sub>O system is probably the most thoroughly researched among all those compounds. The saturation vapor pressure of H<sub>2</sub>SO<sub>4</sub> is several orders of magnitude lower in bulk H<sub>2</sub>SO<sub>4</sub>-H<sub>2</sub>O-NH<sub>3</sub> solutions compared with H<sub>2</sub>SO<sub>4</sub>-H<sub>2</sub>O solutions (Marti et al., 1997). On the molecular scale, theoretical ab-initio studies show that NH3 forms strong bonds with H2SO4, greatly enhancing the stability of H<sub>2</sub>SO<sub>4</sub>-containing clusters, both for electrically-neutral and for charged clusters (Kurtén et al., 2007; Ortega et al., 2008, 2012). Generally, these studies predict a maximum base: acid ratio of 1:1, even though the conducted studies have been computationally limited to clusters up to about 8 molecules. Experimentally, small ion clusters of the types  $(NH_3)_m \cdot (H_2SO_4)_n \cdot HSO_4$  and  $(NH_3)_m \cdot (H_2SO_4)_n \cdot NH_4^+$ ,

containing up to about 15 molecules, have been produced in various laboratory setups, allowing studies of their formation and stability (Hanson and Eisele, 2002; Bzdek et al., 2011; Froyd and Lovejoy, 2012). Ratios  $m/n \le 1$  were obtained, in agreement with the theoretical expectations.

Experiments at the Cosmics Leaving OUtdoor Droplets (CLOUD) facility at CERN addressed new particle formation from NH<sub>3</sub>, H<sub>2</sub>SO<sub>4</sub> and H<sub>2</sub>O in an aerosol chamber setup. The results from these experiments connected the same  $(NH_3)_m \cdot (H_2SO_4)_n \cdot ion^{\pm}$  clusters directly to new particle formation at atmospherically relevant rates (Kirkby et al., 2011). Formation rates comparable to those in the ambient atmosphere were only obtained when either H<sub>2</sub>SO<sub>4</sub> concentrations were at least one order of magnitude higher than typical ambient concentrations, or when the temperature was very low (–25 °C), ruling out NH<sub>3</sub>, H<sub>2</sub>SO<sub>4</sub> and H<sub>2</sub>O as the sole participants in new-particle formation in most regions of the atmospheric boundary layer.

Clusters of  $NH_3$ ,  $H_2SO_4$  and  $H_2O$  may nevertheless play an important role in the very first steps of new-particle formation in the atmosphere. It was recently shown that the critical first step may be the stabilization of small  $H_2SO_4$ -containing clusters by  $NH_3$ , amines or organic compounds (Kulmala et al., 2013). In that study, these stabilized clusters grew relatively slowly up to an activation size (1.5–1.9 nm mobility diameter), and were only then able to grow faster by the enhanced uptake of additional compounds (likely organics). Indeed, the only clusters that have so far been unambiguously identified in the atmosphere and directly linked to new particle formation are clusters of  $H_2SO_4$  plus  $NH_3$  or amines or both (Ehn et al., 2010; Kulmala et al., 2013).

Gaseous  $NH_3$  concentrations vary widely in the atmosphere, both with location and time, from <10 pptv to several ppbv (Ziereis and Arnold, 1986; Janson et al., 2001; Riipinen et al., 2007; Gong et al., 2011; Osada et al., 2011). In particular low concentrations of  $NH_3$  remain challenging to measure accurately in the atmosphere (von Bobrutzki et al., 2010). Atmospheric measurements of other bases, such as amines, suffer from similar problems. However, recent laboratory experiments have shown a great enhancement of the formation of particles from  $H_2SO_4$  by the addition of only either tens

S. Schobesberger et al.

Printer-friendly Version

of pptv of  $NH_3$  (Kirkby et al., 2011) or a few pptv of dimethylamine (Almeida et al., 2013). Therefore, amines are likely to be important for atmospheric particle formation in regions near to amine sources. It remains to be determined which base is the dominant stabilizer of  $H_2SO_4$ -containing clusters in the atmospheric boundary layer. Some theoretical studies suggest that the stabilizing effect of  $NH_3$  dominates for typical atmospheric conditions due to low gas-phase amine concentrations (Nadykto et al., 2011). Indeed, such dominance of the stabilizing effect of  $NH_3$  appears to be supported by the observation that clusters during new particle formation in the boreal forest contain more  $NH_3$  than dimethylamine (Schobesberger et al., 2013a). Another experimental study reported on the important role of small bases in new particle formation in Mexico City and Atlanta (Chen et al., 2012). The stabilizing effect due to  $NH_3$  could not be differentiated from the effect due to amines, but  $NH_3$  concentrations were found to clearly exceed amine concentrations.

This paper presents a comprehensive set of observations of clusters containing mainly  $H_2SO_4$  and  $NH_3$  during new particle formation experiments at the CLOUD facility at CERN. These are growing ion clusters, negatively or positively charged, that directly lead to the formation of aerosol particles in the CLOUD aerosol chamber (Kirkby et al., 2011; Keskinen et al., 2013). The chamber features precise control of experimental parameters and exceptional cleanliness. It provides environments with very low levels of contaminants (Schnitzhofer et al., 2013) and allows for the exploration of a wide range of conditions including very low concentrations of critical trace vapors such as  $NH_3$  and amines.

The main goal of this work is to provide a comprehensive picture on the role of  $NH_3$  in the initial cluster formation, and eventually of new-particle formation, in the  $NH_3$ - $H_2SO_4$ - $H_2O$  system. The specific scientific questions we aim to answer here include (1) what is the detailed molecular structure of the observed clusters under different atmospherically relevant conditions, (2) what are the roles of  $NH_3$  and  $H_2SO_4$  concentrations and temperature in determining the cluster composition, and thereby the plausible cluster formation mechanism, especially at the limits of low and high  $NH_3$  to

H<sub>2</sub>SO<sub>4</sub> gas concentration ratios, and (3) how the clusters are affected by trace amounts of other bases, such as amines, that are usually present as contaminants in experimental systems. We will also discuss the role of different charge carriers involved in these kinds of cluster measurements, and compare our observations with field observations 5 and theoretical expectations. We approached the problem by investigating both negatively and positively charged ions and ion clusters up to 3300 Th, corresponding to up to about 2.1 nm in mobility-equivalent diameter, by using a high-resolution ion mass spectrometer. Our experimental conditions ranged from -25 to +20 °C for temperature, 21 to 90% for relative humidity (RH), <5 to > 1000 pptv for NH<sub>3</sub> concentration, and  $3 \times 10^6$  to  $1 \times 10^9$  cm<sup>-3</sup> for H<sub>2</sub>SO<sub>4</sub> concentration.

#### Methods

The results presented here are based on the CLOUD 2 (June and July 2010) and CLOUD 3 (October and November 2010) campaigns at the CLOUD chamber at CERN.

#### The CLOUD chamber 2.1

A description of the general experimental setup is given in more detail in Kirkby et al. (2011). The CLOUD chamber is a cylindrical stainless-steel container with an inner volume of 26.1 m<sup>3</sup>. It is filled with air (79% nitrogen, 21% oxygen) that is obtained from the evaporation of cryogenic liquids, plus trace gases. Ozone (O<sub>3</sub>) concentrations in the chamber ranged from 200 to 1000 ppbv. RH was varied between 21 and 90%, but mostly kept at 37 to 41%. The trace gases sulfur dioxide (SO<sub>2</sub>) and NH<sub>3</sub> can be added on demand via individual independent lines. Fresh humidified air and trace gases are fed into the chamber continuously at a total rate of 85 L min<sup>-1</sup>, while air is extracted by the measuring instruments. The chamber is usually operated at an overpressure of 5 mbar to avoid contamination from outside the chamber. A pair of fans facilitates the mixing of the chamber contents (Voigtländer et al., 2012). The inside of **ACPD**

Title Page **Abstract** Introduction Conclusions References **Tables Figures** Back Close

Printer-friendly Version

the chamber can be irradiated by UV light from the top of the chamber (Kupc et al., 2011). This UV light induces photolytic reactions, in particular the oxidation of  $SO_2$  (at concentrations of 15 to 34 ppbv) to form  $H_2SO_4$ . The temperature inside the chamber is actively controlled and stable within 0.01 °C for the typical length of an experiment.

Some ionization always occurs inside the chamber via natural galactic cosmic rays (GCR). In addition, the chamber can be exposed to 3.5 GeV c<sup>-1</sup> pions ( $\pi^+$ ) that are provided by the CERN Proton Synchrotron in one to three spills per minute. The intensity of the spills can be regulated, and the mean total ion pair production rate in the chamber is therefore adjustable between 2 cm<sup>-3</sup> s<sup>-1</sup> ( $\pi^+$  beam off) and 42 cm<sup>-3</sup> s<sup>-1</sup> (at the usual maximum available  $\pi^+$  beam intensity). An electrical clearing field of 20 kV m<sup>-1</sup> can be applied by means of a pair of field cage electrodes, mounted at the top and the bottom of the chamber. This field will sweep out all ions in the chamber in about one second, providing an environment practically free of ions, when needed.

During the CLOUD 2 and CLOUD 3 campaigns, a wide array of instruments was arranged around the chamber, continuously analyzing its contents via 16 sampling probes. These sampling probes were mounted radially around the chamber and projected 0.5 m into the chamber. The instrumentation included an atmospheric pressure interface time-of-flight (APi-TOF) mass spectrometer to measure the chemical composition of ions (up to about 2 nm in size). Results from the APi-TOF are the main subject of this study, and the instrument is described below. The rest of the instrumentation included an Airborne Neutral cluster and Air Ion Spectrometer (NAIS) (Mirme et al., 2010), used to measure ions from 0.8 to 40 nm in mobility-equivalent diameter. A comprehensive suite of particle counting and sizing instruments facilitated aerosol number size distribution measurements, covering the range from 1.3 to 100 nm (Kirkby et al., 2011). A chemical ionization mass spectrometer (CIMS) (Kürten et al., 2011, 2012) measured H<sub>2</sub>SO<sub>4</sub> concentrations down to about 10<sup>5</sup> cm<sup>-3</sup> at an accuracy of +100 %/-50 %. During CLOUD 3 only, a proton transfer reaction mass spectrometer (PTR-MS) (Norman et al., 2007) and a LOng Path Absorption Photometer (LOPAP) (Bianchi et al., 2012) were used to measure NH<sub>3</sub> concentrations down to 35 pptv.

Interactive Discussion

The APi-TOF sampled air from the CLOUD chamber using one of the radially mounted sampling probes. The sampling probe's inner diameter (ID) was 22.1 mm and its total length was 1.2 m, of which 0.5 m projected into the chamber. The APi-TOF shared the same sampling probe with the NAIS. The total sample flow from the chamber of  $27.8 \, \text{L} \, \text{min}^{-1}$  (at  $-24 \, ^{\circ}\text{C}$ ) to  $34.5 \, \text{L} \, \text{min}^{-1}$  (at  $19 \, ^{\circ}\text{C}$ ) was split at  $45 \, ^{\circ}$  using a Y-splitter (Fig. 1). The flow from the Y-splitter to the APi-TOF (9.8 to  $11.5 \, \text{L} \, \text{min}^{-1}$ ) was directed at the APi-TOF's orifice inlet, where  $0.8 \, \text{L} \, \text{min}^{-1}$  were drawn into the instrument and the rest discarded.

#### 2.3 The APi-TOF

The APi-TOF is a time-of-flight mass spectrometer built by Tofwerk AG and Aerodyne Research, Inc. A detailed description of the instrument and its capabilities is found in Junninen et al. (2010). The APi-TOF is designed to measure the mass-to-charge ratio of ambient ions of either positive or negative polarity. No ionization of the sample is performed, so only ions that are formed in the CLOUD chamber are detected. Air is sampled directly from atmospheric pressure via a critical orifice. In the interface (APi), ions are focused and guided through differentially pumped chambers to the time-of-flight mass spectrometer (TOF), where the pressure is reduced to  $10^{-6}$  mbar.

During CLOUD 2 and CLOUD 3, the mass accuracy was better than 10 ppm. The resolving power (determined from the peak width at half maximum) was up to 4900 Th Th<sup>-1</sup> (CLOUD 2) or up to 5300 Th Th<sup>-1</sup> (CLOUD 3) for negative ions, and up to 4300 Th Th<sup>-1</sup> for positive ions. The instrument was set to obtain mass-to-charge ratios up to either about 2115 Th (in positive mode and some experiments in negative mode) or 3300 Th (most experiments in negative mode). At all times during these measurements, the APi-TOF detected only singly charged ions, therefore the unit thomson (Th) can also be thought of as atomic mass unit (u) or dalton (Da). To provide a comparison with condensation particle counters and mobility spectrometers, a singly charged

Interactive Discussion

ammonium bisulfate cluster ion at 3300 Th corresponds to about 2.1 nm in mobility-equivalent diameter, using the conversion procedure described by Ehn et al. (2011). The APi-TOF's ion transmission efficiency was set to have its maximum at about 900 to 1400 Th for negative ions, and at about 100 to 300 Th for positive ions. In the CLOUD campaigns, we recorded spectra at a time resolution of 5 s. The signal-to-noise ratio usually resulted in a maximum practical time resolution of 30 s.

Sampled ions may be subject to fragmentation inside the APi-TOF. Such fragmentation was mainly manifest by the usual near-absence of any H<sub>2</sub>O clustered with, for instance, sulfuric acid. The evaporation rate of H<sub>2</sub>O from these clusters is too rapid to survive detection in the non-equilibrium environment of the APi-TOF. However, many more strongly bound clusters can be detected, as will be shown here and has been shown before (e.g., Ehn et al., 2010; Junninen et al., 2010). Also, comparisons with ion mobility spectrometers demonstrate a good agreement with the APi-TOF's results (Ehn et al., 2011; Schobesberger et al., 2013a). Comparisons between the APi-TOF and the NAIS for our measurements produce a similar agreement, so the ion mass spectra obtained by the APi-TOF are, in general, representative of the actual population of small ions and ion clusters. However, a few molecules may anyway be lost from clusters during the sampling, as has also been suggested by comparisons between APi-TOF results and cluster simulations (Olenius et al., 2013b; Ortega et al., 2014).

The data obtained from the APi-TOF measurements were processed and analyzed using tofTools, a software package based on MATLAB and under continuous development, mainly at the University of Helsinki. Details on the analysis of APi-TOF data are found elsewhere (Schobesberger et al., 2013a).

### 2.4 Gas-phase concentrations of NH<sub>3</sub>

The primary means of obtaining the gas-phase concentration of  $NH_3$  ([NH $_3$ ]) were the results from the LOPAP (Bianchi et al., 2012). It was only available during CLOUD 3 and above 0 °C. Below 0 °C, measurements of [NH $_3$ ] were available from the PTR-MS

Discussion Paper

for some experiments in CLOUD 3. Ammonia concentrations could also be estimated from the calibrated mass flow controller settings.

In practice,  $[NH_3]$  was directly measured whenever  $NH_3$  had been added during most of the CLOUD 3 campaign. Without the deliberate addition of  $NH_3$ , values of  $[NH_3]$  were below the detection limit of 35 pptv. More refined measurements during later campaigns showed that this contaminant level of  $[NH_3]$  was in fact likely <2 pptv for experiments at 5 °C (Almeida et al., 2013). The most plausible source of this contaminant  $NH_3$  was evaporation from the inside walls of the chamber. Therefore, we assumed that contaminant levels of  $[NH_3]$  were 2 pptv at 5 °C and directly proportional to the desorption rate of  $NH_3$ , assuming an activation energy of 33 kJ mol<sup>-1</sup>. Thus calculated contaminant levels of  $[NH_3]$  ranged from 0.3 pptv (at -24.7 °C) to 4.3 pptv (at 19.7 °C).

Ammonia concentrations also had to be calculated for a selection of experiments below 0  $^{\circ}$ C when no direct measurement results of [NH $_3$ ] were available. In the beginning of these experiments, [NH $_3$ ] was above contaminant levels, but no NH $_3$  was being added to the chamber anymore. Therefore, a decay of [NH $_3$ ] as measured previously by the LOPAP was used for our calculations, in addition to the proportionality to the desorption rate.

During the few experiments when NH<sub>3</sub> was added during CLOUD 2, estimates for [NH<sub>3</sub>] were made using the settings of the mass flow controllers that control the gas flows into and out of the CLOUD chamber.

### 2.5 Ambient measurements in the boreal forest

The same APi-TOF as in the CLOUD campaigns was deployed also at the Station for Measuring Ecosystem-Atmosphere Relations (SMEAR II) (Hari and Kulmala, 2005), where it measured negatively charged ions during spring 2011. The SMEAR II station is located in Hyytiälä, southern Finland, within a boreal forest, with Tampere being the closest larger town, 50–60 km southwest of the station. The station is the site of a host of continuing atmospheric observations, which includes extensive aerosol

measurements that can be used to detect and analyze new particle formation events (Kulmala et al., 2004a). For the results shown in this study, [NH<sub>3</sub>] was measured by a Monitoring instrument for Aerosols and Gases (MARGA) (Makkonen et al., 2014), and [H<sub>2</sub>SO<sub>4</sub>] was measured by a CIMS, similar to the one used at the CLOUD experiments.

The APi-TOF was situated inside a container in the forest, directly sampling ambient air in a setup similar to that used at the CLOUD chamber (details in Schobesberger et al., 2013a). It should be noted that the APi-TOF was tuned differently for those measurements, resulting in a reduced ion transmission efficiency at high m/z compared to the experiments at CLOUD.

#### 3 Results

# 3.1 Negatively charged ions during new particle formation experiments from $H_2SO_4$ (no NH<sub>3</sub> added)

A typical new particle formation experiment in the CLOUD chamber starts with the UV lights being turned on, leading to a marked increase of  $[H_2SO_4]$  (Fig. 2a), which in turn triggers new particle formation. The formation and subsequent growth of particles was measured by the particle or ion counting and sizing instrumentation, including the NAIS (Fig. 2b). For most of the investigated gas mixtures, the NAIS showed that ion-induced nucleation was only or predominantly proceeding in negative polarity. Therefore the APi-TOF was mostly run in the negative mode (for detecting negatively charged ions) during both campaigns. Naturally, the main focus of this study also lies on negatively charged ions.

The APi-TOF measurements provide high-resolution mass spectra of ions and ion clusters up to about 2.1 nm in mobility-equivalent diameter, capturing exactly the critical first steps of the ion-induced pathway of new particle formation (illustrated in Fig. 2b). The elemental compositions of ions are identified primarily by their exact

mass. Therefore, it is advantageous to present mass spectra as mass defect diagrams (Fig. 2c). In such a diagram, the mass defect for each ion, i.e. the deviation from its nominal mass, is plotted against its mass-to-charge ratio. Any given ion will occupy a unique position in this diagram, and an addition of a specified atom or molecule will move an ion by a characteristic vector (e.g., see Fig. 2c insert).

During a typical new particle formation experiment in the CLOUD chamber, the dominant negatively charged ions were small sulfuric acid anion clusters, with the strongest signal, in most cases, from the trimer,  $({\rm H_2SO_4})_2 \cdot {\rm HSO_4^-}$  (Fig. 2c). Heavier ion clusters (>350 Th; containing >3 sulfur atoms) were considerably less abundant for most experimental conditions. These heavier clusters consisted mostly of  ${\rm H_2SO_4}$  molecules. However, they were observed not only as "pure" sulfuric acid clusters but also as clusters with base molecules, specifically molecules of  ${\rm NH_3}$  or of various organic bases, mainly amines.

In general, larger clusters contained more base molecules. The predominant base in these clusters was NH<sub>3</sub>, yielding clusters of the form  $(NH_3)_m \cdot (H_2SO_4)_n \cdot HSO_4^-$  (Fig. 2c). Only certain numbers of NH<sub>3</sub> molecules (m) were seen for each number of H<sub>2</sub>SO<sub>4</sub> molecules (n), depending on experimental conditions. This dependency will be discussed below in more detail. Note that neither NH<sub>3</sub> nor amines had been deliberately fed into the chamber for these experiments. Instead, they were unintended impurities.

Some of the negatively charged clusters that grew by the addition of  $H_2SO_4$  and base molecules had an additional oxygen atom (Fig. 2c). This can be explained by the growth starting from  $HSO_5^-$  instead of  $HSO_4^-$ . The role of  $HSO_5^-$ , as opposed to  $HSO_4^-$ , in the composition and growth of ion clusters, as well as its origin, will be described and discussed in Sects. 3.2 and 4.2.

Note that the APi-TOF did not detect any growing positively charged clusters under the typical experimental conditions discussed in this section, i.e. when no NH<sub>3</sub> was fed into the chamber, temperature was either 5 or 19 °C and RH was 40 %. This is

consistent with simultaneous NAIS measurements that did not show any growth starting from small positively charged ions (<2.5 nm).

### 3.2 Charge carriers different from HSO<sub>4</sub>

Practically all anion clusters that included the bisulfate ion (HSO<sub>4</sub><sup>-</sup>) were also observed in the form where HSO<sub>4</sub><sup>-</sup> was replaced either with HSO<sub>5</sub><sup>-</sup> or, to a lesser extent, with SO<sub>5</sub><sup>-</sup>. The HSO<sub>5</sub><sup>-</sup> and SO<sub>5</sub><sup>-</sup> ions appear to be less efficient than HSO<sub>4</sub><sup>-</sup> in forming the initial clusters with H<sub>2</sub>SO<sub>4</sub> molecules, because

$$[\mathsf{H}_2\mathsf{SO}_4\cdot\mathsf{HSO}_4^-]/[\mathsf{HSO}_4^-] > [\mathsf{H}_2\mathsf{SO}_4\cdot\mathsf{HSO}_5^-]/[\mathsf{HSO}_5^-] > [\mathsf{H}_2\mathsf{SO}_4\cdot\mathsf{SO}_5^-]/[\mathsf{SO}_5^-]$$

The concentrations of  $HSO_5^-$  and  $SO_5^-$  in CLOUD were particularly high compared to the concentration of  $HSO_4^-$  when the concentration of  $H_2SO_4$ , the dominant precursor of  $HSO_4^-$ , was low. The relative amounts of charge carriers were also affected by the  $\pi^+$  beam intensity, i.e. the total ion concentration, and the  $O_3$  concentration: higher beam intensity led to a higher fraction of  $HSO_5^-$  ions, whereas practically no  $HSO_5^-$  or  $SO_5^-$  was observed in experiments without  $O_3$  present in the CLOUD chamber. In addition, the abundance of  $HSO_5^-$ -based ion clusters relative to  $HSO_4^-$ -based clusters in CLOUD increased chiefly together with an increasing role of  $NH_3$ . In the most extreme case, i.e. high  $[NH_3]$ , low  $[H_2SO_4]$  and high beam intensity, about 60 % of the large clusters (those containing 5–19 S atoms) were associated with  $HSO_5^-$ . A maximum of 7 % of the larger clusters was associated with  $SO_5^-$ , and a maximum of <3 % with  $H_2O_{11}NS_2^-$ , probably in the form  $H_2S_2O_8 \cdot NO_3^-$ .

The cluster compositions were very similar regardless of which ion was carrying their charge. The most important difference between the different charge carriers was that we observed  $\text{NH}_3 \cdot (\text{H}_2 \text{SO}_4)_2 \cdot \text{HSO}_5^-$  clusters, whereas the smallest ammonia-containing cluster associated with  $\text{HSO}_4^-$  was  $\text{NH}_3 \cdot (\text{H}_2 \text{SO}_4)_3 \cdot \text{HSO}_4^-$ . The counts for  $\text{NH}_3 \cdot (\text{H}_2 \text{SO}_4)_2 \cdot \text{HSO}_5^-$  clusters was usually more than an order of magnitude lower than the number of similar clusters with one more  $\text{H}_2 \text{SO}_4$  molecule,

 $NH_3 \cdot (H_2SO_4)_3 \cdot HSO_5^-$ , whereas the cluster  $NH_3 \cdot (H_2SO_4)_2 \cdot HSO_4^-$  was totally absent. Subsequently, the average ratio between the number of  $NH_3$  molecules (m) and the number of  $H_2SO_4$  molecules (n) was initially higher in  $HSO_5^-$ -based clusters than in the corresponding  $HSO_4^-$ -based clusters. However, this difference decreased with an increasing cluster size, disappearing or staying approximately constant at about  $n \ge 9$ . The implications of these observations will be discussed in Sect. 4.2.

### 3.3 Contaminant amines in growing anion clusters

No amines were deliberately added into the chamber for the experiments discussed here, i.e. during the CLOUD 2 and CLOUD 3 campaigns. Amine contamination originated probably from the same source as  $NH_3$  (see Sect. 2.4). We can give some estimate of the contaminant levels of the dominant amine,  $C_2H_7N$ , based on measurements from later CLOUD campaigns when dimethylamine was also added into the chamber in several experiments (Praplan et al., 2012; Almeida et al., 2013). These estimates are based on direct measurements of dimethylamine concentrations down to 0.2 pptv at the later experiments, and on measurements of the content of  $C_2H_7N$  in clusters seen by the APi-TOF. Based on those results, we speculate that gas-phase contaminant concentrations of  $C_2H_7N$  were between 0.1 and 1 pptv during the CLOUD 2 campaign, and about 0.1 pptv or even less during the CLOUD 3 campaign.

In the experiments discussed here, the highest abundance of the clusters containing contaminant organic bases (amines or amides) was usually seen on those clusters that contained a sulfuric acid tetramer anion. These clusters were observed either without any base, such as  $(H_2SO_4)_3 \cdot HSO_4^-$ , or clustered with NH3, or clustered with a basic organic compound. The most abundantly-observed organic base has the formula  $C_2H_7N$  (dimethylamine or ethylamine). Other bases observed in these clusters were  $CH_5N$  (methylamine),  $CH_4N_2O$  (urea) and larger amines or amides (Fig. 3). Note that in some cases, we are unable to resolve whether one oxygen atom was part of the organic constituent or whether the ion was  $HSO_5^-$  instead of  $HSO_4^-$ .  $C_2H_7N$  was also

seen to be bound to the sulfuric acid trimer anion, forming  $C_2H_7N\cdot (H_2SO_4)_2\cdot HSO_4^-$ , although with a signal about two orders of magnitude smaller than that of the cluster  $C_2H_7N\cdot (H_2SO_4)_3\cdot HSO_4^-$ . Notably, the corresponding cluster with  $NH_3$  instead of the amine,  $NH_3\cdot (H_2SO_4)_2\cdot HSO_4^-$ , was not observed.

Also the clusters containing amines (or other organic bases) grew by the accretion of  $H_2SO_4$  and  $NH_3$  molecules at the contaminant levels of amines ( $[C_2H_7N] < 1$  pptv): increasingly larger clusters of the type  $Y \cdot (NH_3)_m \cdot (H_2SO_4)_n \cdot HSO_4^-$  were formed, where Y was almost always only one N-containing organic compound, and at maximum two such compounds ( $(C_2H_7N)_2$  or  $CH_5N \cdot C_2H_7N$ ). In addition, the fraction of clusters that included N-containing organic compounds was smaller for larger clusters ( $n \ge 4$ ) (Figs. 2c and 3).

# 3.4 Composition of NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub>-clusters under different experimental conditions

In all experimental conditions, clusters with more than 4 or 5 sulfur atoms grew by the accretion of NH $_3$  and H $_2$ SO $_4$  molecules, forming progressively larger (NH $_3$ ) $_m \cdot (H_2$ SO $_4$ ) $_n \cdot H$ SO $_4^-$  clusters. The number of added NH $_3$  molecules per added H $_2$ SO $_4$  molecule remained constant from 4 or 5 sulfur atoms up to the upper detection limit of about 27 sulfur atoms, within the measurement uncertainties.

We define the number of added NH<sub>3</sub> molecules per added H<sub>2</sub>SO<sub>4</sub> molecule as  $\Delta m/\Delta n$ . We found that  $\Delta m/\Delta n$  is well suited to describe the whole anion spectra during new particle formation events in the NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub>-system: two spectra with the same  $\Delta m/\Delta n$  were practically identical (unless  $\Delta m/\Delta n$  was close to zero, see Sect. 3.5), and  $\Delta m/\Delta n$  was only dependent on the ratio between the NH<sub>3</sub> and H<sub>2</sub>SO<sub>4</sub> gas-phase concentrations, i.e. on [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>], for a given temperature and RH (Fig. 4). In our analysis, values of  $\Delta m/\Delta n$  were calculated over the range  $4 \le n \le 18$ , because  $\Delta m/\Delta n$  was approximately constant for  $n \ge 4$  and we obtained a signal from clusters up to at least n = 18 in most of the experiments.

Interactive Discussion

At a given temperature and RH,  $\Delta m/\Delta n$  generally increased with an increasing value of [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>], then flattened off when approaching the value of 1, and eventually reached a saturation value slightly larger than 1. At 19°C, the maximum value of  $\Delta m/\Delta n$  of 1.1 to 1.2 was reached at the concentration ratio  $[NH_3]/[H_2SO_4] \approx 100$ (Fig. 4). This concentration ratio was roughly coincident with the threshold for observing cation clusters (at 19 °C and 40 % RH) of the form  $(NH_3)_m \cdot (H_2SO_4)_n \cdot NH_4^+$  with  $m \approx$ n and  $\Delta m/\Delta n \geq 1$ . In an analogous way, the NAIS observed a formation of positively charged ions only when positively charged NH3-H2SO4 clusters were observable by the APi-TOF. Note that for the cation clusters,  $\Delta m/\Delta n$  was constant already from n=1onward and it was generally calculated over the range  $1 \le n \le 17$ .

The relationship between  $\Delta m/\Delta n$  and  $[NH_3]/[H_2SO_4]$  was similar under all experimental conditions, but the exact functional form of this relation was temperature dependent (Fig. 5a). For example, the value of  $\Delta m/\Delta n = 0.2$  was reached at  $[NH_3]/[H_2SO_4] \approx 0.1$  when the temperature was 19°C, at  $[NH_3]/[H_2SO_4] \approx 0.7$  when it was 5 °C, and at  $[NH_3]/[H_2SO_4] > 1$  when it was -25 °C. Also, the maximum observed values of  $\Delta m/\Delta n$  seemed to be reached at lower values of  $[NH_3]/[H_2SO_4]$ , and these maximum values were slightly higher at lower temperatures (e.g. a maximum  $\Delta m/\Delta n$ of 1.1 to 1.2 at 19 °C, vs. a maximum  $\Delta m/\Delta n$  of 1.3 at -25 °C).

Note that in practically all our experiments at  $[NH_3]/[H_2SO_4] < 1$ , only contaminant levels of [NH<sub>3</sub>] were present. These contaminant levels were not directly measured, but calculated under the assumptions described in Sect. 2.4. In particular the temperature dependence of these low values of [NH<sub>3</sub>] is subject to those assumptions. Note also that most experiments at CLOUD were run with the RH between 37 and 41 %, so the potential RH effects could not be thoroughly investigated. However, an increase of RH to >68 % increased the value of  $\Delta m/\Delta n$  (Fig. 4). No significant effect on negatively charged clusters was observed due to RH changes in the range 30 % < RH < 60 %.

On the composition of ammonia-sulfuric acid clusters

S. Schobesberger et al.

Title Page **Abstract** Introduction Conclusions References **Tables Figures** Back Close Full Screen / Esc

The role of NH<sub>3</sub> in the formation of clusters became negligible at very low values of [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>], i.e. when  $\Delta m/\Delta n$  dropped below 0.1 and the formation of pure binary clusters dominated (Fig. 5). Binary cluster formation is observed by the APi-TOF as pure sulfuric acid anion clusters, (H<sub>2</sub>SO<sub>4</sub>)<sub>n</sub>·HSO<sub>4</sub><sup>-</sup>, because H<sub>2</sub>O molecules are lost in the sampling process (Sect. 2.3). The fraction of pure, NH<sub>3</sub>-free sulfuric acid clusters was calculated over the same cluster range as was used for calculating  $\Delta m/\Delta n$  ( $4 \le n \le 18$ ), and like  $\Delta m/\Delta n$ , it was a function of [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>]. The fraction of NH<sub>3</sub>-free sulfuric acid clusters increased with a decreasing value of [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>], and such clusters were observed only below some temperature-dependent threshold value of [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>] (Fig. 5b). Taken together, the presence of pure, NH<sub>3</sub>-free sulfuric acid clusters was favored by lower [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>] ratios and lower temperatures.

Note that the  $NH_3$  contamination in the CLOUD chamber sets a lower limit to the minimum level of  $[NH_3]$  that can be achieved. Therefore, pure binary sulfuric acid-water cluster formation can only be obtained at a sufficiently high  $[H_2SO_4]$  level or at low temperatures. A low temperature both decreases the contaminant level of  $[NH_3]$  (Sect. 2.4) and increases the threshold  $[NH_3]/[H_2SO_4]$  below which binary cluster formation occurs (Fig. 5b).

#### 4 Discussion

# 4.1 The composition of negative ions during new particle formation experiments (no NH<sub>3</sub> added)

Without adding any  $NH_3$  into the CLOUD chamber, most anions during a new particle formation experiment in the CLOUD chamber were small sulfuric acid anion clusters. Heavier anion clusters, containing >3 sulfur atoms, were not only "pure" sulfuric acid clusters but also clusters associated with base molecules, namely  $NH_3$  or

Interactive Discussion

various organic bases, mainly amines (Figs. 2c and 3). These findings agree qualitatively with observations made in the ambient atmosphere (Ehn et al., 2010), with independent measurements of such clusters in the laboratory (Bzdek et al., 2011), as well as with the results of simulations that consider classical collisions and evap-5 oration rates based on quantum chemical methods (Olenius et al., 2013b). Both earlier experimental and theoretical studies, as well as our results here, show that NH<sub>3</sub> molecules can only cluster with anionic (= deprotonated) sulfuric acid clusters, i.e. form  $(NH_3)_m \cdot (H_2SO_4)_n \cdot HSO_4$ , if  $n \ge 3$ . This lower size limit for the inclusion of  $NH_3$ molecules is explained by HSO<sub>4</sub> itself acting as an electron donor (= Lewis base), in competition with regular bases such as NH<sub>3</sub>. Only when  $n \ge 3$ , the cluster is acidic enough to accept NH<sub>3</sub> molecules (Ortega et al., 2014).

The observation of both ammonia and amines in these clusters here is remarkable because neither NH<sub>3</sub> nor amines were deliberately fed into the CLOUD chamber for these experiments. All NH<sub>3</sub> and amines were unintended impurities ([NH<sub>3</sub>] < 5 pptv,  $[C_0H_7N] < 1$  pptv), yet they were found to play a crucial role in the chemistry of growing ion clusters.

### The role of charge carriers different from HSO<sub>4</sub>

In order of importance, the charge carriers in the observed base-sulfuric acid clusters were HSO<sub>4</sub>, HSO<sub>5</sub>, SO<sub>5</sub>, and H<sub>2</sub>O<sub>11</sub>NS<sub>2</sub>. The HSO<sub>4</sub> ion strongly correlated with [H<sub>2</sub>SO<sub>4</sub>] and was certainly formed by the de-protonation of H<sub>2</sub>SO<sub>4</sub>. A formation mechanism for SO<sub>5</sub> has been investigated by Möhler et al. (1992). The initial step of this mechanism is the formation of SO<sub>3</sub> from SO<sub>2</sub> by the transfer of O<sup>-</sup> from O<sub>3</sub>. Subsequently,  $SO_5^-$  forms from  $SO_3^-$  and  $O_2$  with a mediating  $N_2$  or  $H_2O$ . We observed that  $O_3$ in the CLOUD chamber was required for the formation of both SO<sub>5</sub> and HSO<sub>5</sub>, supporting these or similar ion-molecule reactions as a source. Possible origins of the HSO<sub>5</sub> ions were the electronic charging of HSO<sub>5</sub>, while HSO<sub>5</sub> itself had possibly been formed as described in Kurtén et al. (2009), a proton-transfer reaction with peroxymonosulfuric

### **ACPD**

### On the composition of ammonia-sulfuric acid clusters

S. Schobesberger et al.

acid  $H_2SO_5$ , or ion-molecule reactions similar to those probably leading to the formation of  $SO_5^-$ .  $H_2O_{11}NS_2^-$  was probably  $H_2S_2O_8 \cdot NO_3^-$ .  $H_2S_2O_8$  might have been formed from hydrated  $SO_5$  or from  $HSO_5$  (Kurtén et al., 2009). Nitric acid (HNO $_3$ ) and its conjugate base  $NO_3^-$  were present as contaminants in the chamber.

By far the most abundant ions during the new particle formation experiments at CLOUD that are discussed here were the clusters of type  $(NH_3)_m \cdot (H_2SO_4)_n \cdot HSO_4$ and  $(NH_3)_m \cdot (H_2SO_4)_n \cdot HSO_5^-$ . The latter type gains relevance in conditions of high  $[NH_3]$ . Ammonia was present at  $n \ge 2$  in the  $HSO_5^-$ -based clusters but at  $n \ge 3$  in the HSO<sub>4</sub>-based clusters. This suggests that sulfuric acid ion clusters will cluster more readily (i.e., build more stable clusters) with NH<sub>3</sub> when the charge-carrying component is  $HSO_5^-$  instead of  $HSO_4^-$ . Most likely, this was the primary reason for the observed increase of the fraction of HSO<sub>5</sub>-based clusters at higher values of [NH<sub>3</sub>]. A secondary reason was the usually coincidental lower  $[H_2SO_4]$  during such experiments. The only other difference to the  $HSO_{\Delta}^{-}$ -based clusters was an initially higher ratio m/n, as a direct consequence of the acceptance of NH<sub>3</sub> molecules already at n = 2. Otherwise however, the composition of the clusters was the same, and the prevalent mechanism of cluster growth was not affected, namely the addition of a certain number of NH<sub>3</sub> molecules per H<sub>2</sub>SO<sub>4</sub> molecule. Therefore, we conclude that the presence and actions of charge carriers other than HSO<sub>4</sub> do not alter the conclusions of this study. Interestingly, when  $n \ge 9$ , differences in the ratio m/n disappeared or became approximately constant, suggesting that at about that size the ion cluster had become large enough to render any chemical effect of its charge-carrying component unimportant.

In conclusion, we suggest that  $HSO_5^-$  is a somewhat weaker Lewis base than  $HSO_4^-$ . Therefore, clusters containing  $HSO_5^-$  take up more readily bases and less readily acids, as compared with clusters containing  $HSO_4^-$ , which is in line with all our observations. Furthermore, the highest prevalence of  $HSO_5^-$  in all experiments at the CLOUD chamber to date has been in the dimethylamine- $H_2SO_4$  anion clusters that were produced during later experiments (in 2011 and 2012) following the addition of dimethylamine, a stronger base than  $NH_3$  (Almeida et al., 2013).

Throughout our experiments, contaminant levels of amines were below the limit of direct detection. We estimate the gas-phase contaminant concentrations of  $C_2H_7N$  between 0.1 and 1 pptv during the CLOUD 2 campaign, and about 0.1 pptv during the CLOUD 3 campaign, but they may have been even smaller. The most abundant contaminant amine observed in anionic clusters was  $C_2H_7N$ , and the most abundant cluster containing  $C_2H_7N$  was  $C_2H_7N \cdot (H_2SO_4)_3 \cdot HSO_4^-$  (Fig. 3). Note that  $C_2H_7N \cdot (H_2SO_4)_2 \cdot HSO_4^-$  was observed, whereas  $NH_3 \cdot (H_2SO_4)_2 \cdot HSO_4^-$  was not. Nevertheless, the growth of the clusters at contaminant levels of amines proceeded almost exclusively by the addition of  $NH_3$  and  $H_2SO_4$  molecules. The resultant dominant role of  $NH_3$  in the growth of the clusters, as opposed to organic bases (amines or amides), is most likely due to the differences in respective contaminant level concentrations ([NH3] about 2 to 4 pptv, [C2H7N] < 1 pptv).

The effect of higher gas-phase concentrations of amines, in particular of dimethylamine, on the composition of growing clusters and on particle formation rates has since been thoroughly investigated in subsequent CLOUD campaigns (Almeida et al., 2013). A large influence on cluster formation and particle formation rates was found at dimethylamine concentrations as low as 3 pptv. Specifically, growing ion clusters consisted of practically only dimethylamine and  $H_2SO_4$ , and particle formation rates were significantly enhanced. The enhancement of particle formation rates in those experiments was due to dimethylamine being a stronger base than  $NH_3$  and consequently forming more stable bonds with  $H_2SO_4$  molecules. The same reason can account for the observation (here, as in Almeida et al., 2013) that dimethylamine binds first to the sulfuric acid trimer anion, whereas  $NH_3$  requires one more  $H_2SO_4$  in the cluster and binds first to the sulfuric acid tetramer anion. Specifically, dimethlyamine competes more successfully than  $NH_3$  against  $HSO_4$ , which acts as a strong Lewis base in these clusters.

However, in the experiments presented here, no effect on the rate of new particle formation was observed due to the contaminant levels of amines (<1 pptv). Also, the composition of the growing ion clusters was dominated by NH<sub>3</sub> and appeared to be unaffected by the optional inclusion of an amine.

Interestingly, a similar dominance of NH<sub>3</sub> over amines is also apparent in the composition of base-sulfuric-acid ion clusters that were observed during new particle formation in the ambient atmosphere, specifically in a boreal forest environment (Kulmala et al., 2013; Schobesberger et al., 2013a). However, it was also shown that other, oxidized organic compounds participate in those atmospheric new particle formation events as well from an early stage on (Schobesberger et al., 2013a; Ehn et al., 2014), suggesting more complex mechanisms of formation and growth of clusters, which have not yet been determined in detail.

# 4.4 The composition of NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> clusters in the CLOUD laboratory experiments

The APi-TOF measurements of  $NH_3$ - $H_2SO_4$  clusters during particle formation experiments at the CLOUD chamber revealed how these clusters grow by the accretion of certain numbers of  $NH_3$  and  $H_2SO_4$  molecules. The measurements covered the range up to clusters containing about 27 sulfur atoms. This maximum size corresponds to 2.1 nm in mobility equivalent diameter, when converted according to Ehn et al. (2011) using the bulk density of ammonium bisulfate (1780 kg m<sup>-3</sup>; and neglecting a likely involvement of  $H_2O$ ).

The anion clusters were mainly of the form  $(NH_3)_m \cdot (H_2SO_4)_n \cdot HSO_4^-$ . The  $HSO_4^-$  ion acts as a strong Lewis base, so stable bonds with  $NH_3$  molecules are only possible for  $n \geq 3$ . For larger clusters  $(n \geq 4)$ , the cluster growth was well characterized by the ratio of added  $NH_3$  molecules per added  $H_2SO_4$  molecule,  $\Delta m/\Delta n$ , which we found to be dependent on the ratio  $[NH_3]/[H_2SO_4]$  and temperature (Fig. 5a). At high enough values of  $[NH_3]/[H_2SO_4]$ ,  $\Delta m/\Delta n$  saturated at just above unity. Note that a ratio of  $\Delta m/\Delta n = 1$  corresponds to the stabilization of each  $H_2SO_4$  molecule by an  $NH_3$

Interactive Discussion

molecule, as in ammonium bisulfate. All these observations make it very likely that the binding of molecules via strong hydrogen bonds between acidic and basic molecules and acid-base reactions were the dominant mechanism in both the initial formation of these clusters and their subsequent growth up to > 2 nm. The basic molecules were 5 the HSO<sub>4</sub> ion and NH<sub>3</sub> molecules, while the acidic molecules were H<sub>2</sub>SO<sub>4</sub> molecules. In terms of cluster composition, therefore, the chemical property of HSO<sub>4</sub> appears to outweigh electrostatic effects due to the electric charge. Consequently, the enhancements of particle formation rates attributed to NH<sub>3</sub> or to a negative charge (Kirkby et al., 2011) may both be the consequence of essentially the same process of acid-base stabilization (Kupiainen et al., 2012).

In Fig. 6 we summarize the characteristics of the observed composition of  $(NH_3)_m \cdot (H_2SO_4)_n \cdot HSO_4^-$  anion clusters as a function of vapor concentration ratio [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>] and temperatures. Pure binary H<sub>2</sub>SO<sub>4</sub>-H<sub>2</sub>O cluster formation was favored by low values of [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>] and low temperatures. From a macroscopic point of view, this temperature dependence is consistent with the differences in the temperature dependences of the saturation vapor pressures of bulk H<sub>2</sub>SO<sub>4</sub> and NH<sub>3</sub>. Namely, the saturation vapor pressure of H<sub>2</sub>SO<sub>4</sub> decreases more steeply than that of NH<sub>3</sub> with decreasing temperature (Vehkamäki et al., 2002; Hodgman, 1962); therefore the ratio of these pressures ( $p_{sat}$ , NH<sub>3</sub>/ $p_{sat}$ , H<sub>2</sub>SO<sub>4</sub>) increases with decreasing temperature.

From a microscopic point of view, the influence of NH<sub>3</sub> vs. H<sub>2</sub>SO<sub>4</sub> vapors on the growing clusters is consistent with a barrier for addition of NH3 to the clusters and barrierless addition of H<sub>2</sub>SO<sub>4</sub>. This has also been deduced from surface-induced cluster dissociation and quantum chemistry (Bzdek et al., 2013). Specifically, the nearsaturation of the NH<sub>3</sub> content of the clusters at  $[NH_3]/[H_2SO_4] > 10$  suggests that roughly 10 collisions of NH<sub>3</sub> with an under-neutralized cluster are necessary to add the base molecule to a growing cluster, or to overwhelm the evaporation rate of NH<sub>3</sub> from the cluster. The presence of a barrier for the NH<sub>3</sub> uptake would be expected to lead to a slower NH<sub>3</sub> uptake at lower temperatures. Such a temperature dependence is

### **ACPD**

### On the composition of ammonia-sulfuric acid clusters

S. Schobesberger et al.

consistent with the increased value of [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>] required at lower temperatures to add NH<sub>3</sub> molecules to under-saturated NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> or H<sub>2</sub>SO<sub>4</sub> clusters (Figs. 5 and 6).

At high values of  $[NH_3]/[H_2SO_4]$ , the ratio  $\Delta m/\Delta n$  usually exceeded 1, approaching saturation in terms of the cluster  $NH_3$  content (Figs. 5a and 6). This relationship appeared independent of the temperature within uncertainties and the investigated temperature range (-25 to  $20\,^{\circ}$ C). However, our data set may not be sufficiently complete to resolve possible dependencies on temperature. In this regime of high values of  $[NH_3]/[H_2SO_4]$ , also cation clusters of the form  $(NH_3)_m \cdot (H_2SO_4)_n \cdot NH_4^+$  were observable, again with  $\Delta m/\Delta n \geq 1$  (Fig. 5a). Note that the anion clusters tended to feature slightly higher saturation values of  $\Delta m/\Delta n$  at lower temperatures. This feature could be an indication of the enhanced evaporation of  $NH_3$  molecules from the clusters at higher temperatures. Indeed, results of computer simulations using the atmospheric cluster dynamics code (ACDC) suggest that there may be a systematic slight underestimation of the  $NH_3$  content of the experimentally observed clusters in these conditions that we cannot exclude (Olenius et al., 2013a, b).

Since both the anion and cation clusters had  $\Delta m/\Delta n$  slightly above unity when  $[NH_3]/[H_2SO_4] \geq 10$ , the clusters become slightly less acidic as they grew. The mass defect diagrams of the corresponding ion mass spectra illustrate the details on the increase of the clusters' base content as they grow (Fig. 7a and b). The anion clusters were seen to grow first by the addition of acids due to the high basicity of  $HSO_4^-$ . From the tetramer onwards ( $\#S \geq 4$ ; see Sect. 4.2 for exceptions), the anions became chemically (not electrically) neutralized, as the clusters grew by the addition of slightly more than one base per acid (Fig. 7b). For the cation clusters,  $NH_3$  was already present for the monomer, i.e.  $NH_3 \cdot H_2SO_4$   $NH_4^+$ , and the clusters grew slightly more basic already from the first step onwards (Fig. 7a). Interestingly, we observed a wider range of the number of  $NH_3$  molecules m for any n in anion clusters than in cation clusters. We hypothesize that this observation follows from the requirement that  $NH_3 \cdot H_2SO_4$  clusters be basic enough to accept an additional proton (therefore becoming or staying positively charged), whereas they need to be acidic enough to donate a proton

(therefore becoming or staying negatively charged). Sulfuric acid can form clusters with only itself (plus H<sub>2</sub>O) much more readily than can NH<sub>3</sub>. Therefore, highly acidic (NH<sub>3</sub>-) H<sub>2</sub>SO<sub>4</sub> clusters can be formed, and they were indeed observed as anion clusters when [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>] was sufficiently low (e.g., Fig. 2c). For these clusters Δ*m*/Δ*n* was < 1, i.e. they continuously became more acidic as they grew. The possibility of such relatively acidic anion clusters leads to the wider range of observed *m* even at relatively high [NH<sub>3</sub>]. On the other hand, the maximum basicity of NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> clusters is apparently limited, even at the highest investigated [NH<sub>3</sub>] (Fig. 5a). Only such relatively basic clusters can be observed as cation clusters.

Note that almost all our experiments were performed at the RH between 37 and 41 %. Indeed, the data presented in Fig. 4 show that the observed  $NH_3$ - $H_2SO_4$  clusters contained more  $NH_3$  at RH > 68 %. It remains a task for future studies to thoroughly investigate how the composition of these clusters changes with changing RH. It is also worth noting that the APi-TOF was set to measure positively charged clusters in only few experiments; only for experiments at 19 °C did these experiments include conditions with  $[NH_3]/[H_2SO_4] < 100$ .

# 4.5 Comparison to the composition of electrically neutral clusters from the ACDC model

In this work we hypothesize that the growth mechanism of  $NH_3$ - $H_2SO_4$  clusters is governed chiefly by hydrogen bonds and ionic bonds formed by acids and bases and the availability of the gas-phase precursors  $NH_3$  and  $H_2SO_4$ . The electrical charge somewhat increases the stability (Olenius et al., 2013a), but most importantly it provides an additional base in the form of  $HSO_4^-$ , whereas the  $NH_4^+$  ion seems to behave neither basic nor acidic. At relatively high  $[NH_3]$ , both positively and negatively charged  $NH_3$ - $H_2SO_4$  clusters grow by adding  $NH_3$  and  $H_2SO_4$  molecules at a ratio of about unity, once the cluster is large enough that the effect of the  $HSO_4^-$  or  $NH_4^+$  ion is neutralized in terms of its basicity or acidity (Figs. 5a, 7a and b). Therefore we would expect electrically neutral clusters to grow by the same mechanism already from the

Interactive Discussion

first bond-formation onwards. At relatively low [NH<sub>3</sub>], only negatively charged clusters were observed in our experiments, growing mainly by the uptake of H<sub>2</sub>SO<sub>4</sub> molecules (Fig. 5a), whereas positively charged clusters were not seen to be formed. Electricallyneutral NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> clusters must form under these conditions as well, since new particle formation occurred also without any ions in the CLOUD chamber (Kirkby et al., 2011).

We could not measure electrically neutral NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> clusters in this study. However, the difficulties in measuring such neutral clusters do not concern computer simulations. ACDC is a kinetic collision and evaporation model to study the formation dynamics and concentrations of molecular (charged and neutral) clusters (McGrath et al., 2012). In this study, we used ACDC to simulate the steady-state distribution of neutral clusters  $(NH_3)_m \cdot (H_2SO_4)_n$  up to m = 5 and n = 5, as described in Almeida et al. (2013). Cluster evaporation rates were calculated from quantum chemical Gibbs free energies of formation of the clusters. We calculated the  $\Delta m/\Delta n$  ratio for the simulated neutral clusters in the same way as for the measured data, covering the different combinations of temperature, [NH<sub>3</sub>] and [H<sub>2</sub>SO<sub>4</sub>] of the measurement conditions. A single neutral H<sub>2</sub>SO<sub>4</sub> molecule was taken as the starting point. The results are shown as dashed lines in Fig. 5a. The results from the simulations of neutral clusters agreed with the measurements of charged clusters in several respects: a maximum  $\Delta m/\Delta n$  of 1.2 to 1.3 was reached at high values of  $[NH_3]/[H_2SO_4]$  and  $\Delta m/\Delta n$  decreased when  $[NH_3]/[H_2SO_4] < 10$ . Over the whole range, the simulations also reproduced the chief dependence of  $\Delta m/\Delta n$  on the ratio [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>] only. At low values [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>], however, the simulated neutral clusters took up much more NH3 as they grew than the measured negatively charged clusters. This discrepancy may arise from the following reasons: (1) H<sub>2</sub>O molecules were not included in the model simulations, though they are abundant at RH = 40 % and may play a more important role at relatively low [NH<sub>2</sub>]; (2) small neutral clusters indeed contain more NH<sub>3</sub> than their negatively charged counterparts. The former reason would imply that H<sub>2</sub>O molecules are able to compete with NH<sub>3</sub> at relatively low [NH<sub>3</sub>] for acting as the critical bases that stabilize sulfuric acid

### **ACPD**

### On the composition of ammonia-sulfuric acid clusters

S. Schobesberger et al.

clusters. The latter reason appears plausible on its own, as it would put the reliance on NH<sub>3</sub> of neutral clusters between that of anion clusters (no NH<sub>3</sub> required) and cation clusters (relatively much NH<sub>3</sub> required).

### 4.6 Comparison of NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> clusters from CLOUD to ambient observations

Negatively charged  $NH_3-H_2SO_4$  clusters are commonly observed during new particle formation events in the boreal forest when using APi-TOF mass spectrometers (Kulmala et al., 2013; Schobesberger et al., 2013a). A typical anion mass spectrum obtained from those ambient APi-TOF measurements is presented in Fig. 7c, with the  $(NH_3)_m \cdot (H_2SO_4)_n \cdot HSO_4^-$  clusters shown colored. The majority of the larger ions (shown in grey) likely contain mainly a variety of oxidized organics, and some probably also  $H_2SO_4$  molecules (Schobesberger et al., 2013a; Ehn et al., 2012). However, most  $H_2SO_4$  molecules in these anion clusters are found in the  $(NH_3-)H_2SO_4$  clusters. Amines are present in some of these clusters as well, but most of the larger of these clusters (n > 3) contain only  $NH_3$  and  $H_2SO_4$ .

Figures 5a and 6 include a comparison of the CLOUD results with the observations of negatively charged NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> clusters during new particle formation events in the boreal forest during spring-time. The ambient measurements were made at conditions comparable to those covered by the CLOUD experiments, with mean values of 4°C for the temperature and 47% for the RH. The NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> clusters from the boreal forest measurements always showed a high NH<sub>3</sub> content, with  $\Delta m/\Delta n > 1$ . The [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>] ratios measured in the boreal forest at the same times were relatively high as well, with [NH<sub>3</sub>] ranging from 28 to 134 pptv (0.8 to 3.6 × 10<sup>9</sup> cm<sup>-3</sup>) and [H<sub>2</sub>SO<sub>4</sub>] from 0.5 to 2.1 × 10<sup>7</sup> cm<sup>-3</sup>. In these terms, therefore, the ambient observations fully agree with the expectations from the laboratory experiments at CLOUD (Figs. 5a and 6). That specific [H<sub>2</sub>SO<sub>4</sub>] range is well within the values of [H<sub>2</sub>SO<sub>4</sub>] during new particle formation events recorded around the world, those values ranging from about  $10^5$  to  $10^8$  cm<sup>-3</sup> (e.g., Kuang et al., 2008). The [NH<sub>3</sub>] range observed during the boreal

forest events appears on the low side, as it is commonly exceeded by measurements of [NH<sub>3</sub>] at many other locations (Ziereis and Arnold, 1986; Janson et al., 2001; Riipinen et al., 2007; Gong et al., 2011; Osada et al., 2011). Therefore, it is likely that atmospheric NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> clusters forming in the warm boundary layer always feature the maximum NH<sub>3</sub> content, i.e.  $\Delta m/\Delta n > 1$ , as most locations of boundary layer observations are likey saturated in [NH<sub>3</sub>] with respect to the growth of NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> clusters.

The binary H<sub>2</sub>O-H<sub>2</sub>SO<sub>4</sub> new particle formation, i.e. with negligible contribution of NH<sub>3</sub>, can only occur in conditions of sufficiently low [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>] or at low temperatures. Therefore, binary H<sub>2</sub>O-H<sub>2</sub>SO<sub>4</sub> new particle formation must be largely restricted to the free troposphere, and relatively cold parts are preferred. Low temperatures can also facilitate appreciable particle formation rates at atmospherically relevant levels of [H<sub>2</sub>SO<sub>4</sub>] without the necessity of additional participating vapors (Kirkby et al., 2011).

### **Summary and conclusions**

We have presented a comprehensive description of the composition of NH3-H2SO4 clusters as a function of environmental variables, in particular concentrations of precursor vapors ([NH<sub>3</sub>] and [H<sub>2</sub>SO<sub>4</sub>]) and temperature. A wide range of atmospherically relevant conditions were covered, with [NH<sub>3</sub>] ranging from <2 to 1400 pptv, [H<sub>2</sub>SO<sub>4</sub>] from  $3.3 \times 10^6$  to  $1.4 \times 10^9$  cm<sup>-3</sup>, and temperature from -25 °C to +20 °C. Our ion cluster measurements covered the size range between 1 and 2 nm (mobility-equivalent diameters).

We found that it is primarily the ratio [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>] that determines the composition of the measured NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> clusters, with the temperature in a secondary role. Positively charged clusters are only observed from a sufficiently high ratio [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>] upwards. From a ratio [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>] of about 10 up to at least 500, both negatively and positively charged clusters grow by the addition of on average 1 to 1.4 NH<sub>3</sub> molecules per each addition of a H<sub>2</sub>SO<sub>4</sub> molecule. The resultant NH<sub>3</sub>/H<sub>2</sub>SO<sub>4</sub> molar ratios are remarkably close to that of ammonium bisulfate (with an NH<sub>3</sub>/H<sub>2</sub>SO<sub>4</sub> molar

Discussion Paper

Printer-friendly Version

Interactive Discussion

ratio of unity). On the other hand, pure binary H<sub>2</sub>O-H<sub>2</sub>SO<sub>4</sub> clusters (without contribution of NH<sub>3</sub>) only form at values of [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>] smaller than about 0.1 (depending also on temperature). In our experiments, these binary clusters were only observed as negatively charged H<sub>2</sub>SO<sub>4</sub> clusters. In the ambient atmosphere, their formation must 5 be largely restricted to higher regions of the troposphere, where NH<sub>3</sub> concentrations are low.

A detailed comparison of model results on the growth of negative, positive and neutral NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> clusters is presented in Olenius et al. (2013a). So far, the quantum chemical data used to calculate the cluster evaporation rates restricted the model simulations to clusters containing up to ten molecules, whereas the APi-TOF measurements could measure negatively and positively charged clusters up to clusters containing >50 NH<sub>3</sub> and H<sub>2</sub>SO<sub>4</sub> molecules. The model simulations and APi-TOF measurements are consistent and in good agreement with each other, particularly for cases of [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>] > 10. Under these conditions, also electrically-neutral NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> clusters grow principally by adding, on average, 1 to 1.4 NH<sub>3</sub> molecules for each added H<sub>2</sub>SO<sub>4</sub> molecule. Note that the recombination of anion and cation clusters can also contribute to the population of neutral clusters (Olenius et al., 2013a; Kontkanen et al., 2013).

In combination, measurement and model results strongly suggest that acid-base interactions are the dominant clustering mechanism for all NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> clusters. These interactions allow for the initial formation of clusters and facilitate additional intermolecular bonds as the clusters grow to 2 nm in size and larger, i.e. sizes that are nowadays accessible by condensation particle counters (Lehtipalo et al., 2014). The presence of an electric charge implies a missing or extra proton, i.e. the creation of a conjugate base or acid. In particular, the basic properties of HSO<sub>4</sub> have an important impact on the composition of the small negatively charged clusters. We identified the HSO<sub>5</sub> ion as an important alternative ion in these clusters for the conditions in the CLOUD chamber. It appears to be slightly less basic than HSO<sub>4</sub> and similarly affects cluster composition. Besides the stabilizing effect of the electric charge on the cluster,

### **ACPD**

### On the composition of ammonia-sulfuric acid clusters

S. Schobesberger et al.

the property of HSO<sub>4</sub> (or HSO<sub>5</sub>) as a Lewis base is probably crucial to the enhancements of particle formation rates attributed to ions (Kirkby et al., 2011).

In the atmospheric boundary layer, the composition of formed  $NH_3$ - $H_2SO_4$  clusters will mostly be in the regime of saturation that we observed with respect to the clusters'  $NH_3$  content, i.e. they will be seen growing by the addition of in average >1  $NH_3$  molecule per added  $H_2SO_4$  molecule. This prediction is due to  $H_2SO_4$  concentrations in the boundary layer being comparatively low, mostly at sub-pptv levels, leading to typical vapor concentration ratios  $[NH_3]/[H_2SO_4]$  of larger than 10. Ambient APi-TOF measurements during new particle formation events in the Finnish boreal forest indeed confirm this prediction.

Another general requirement for the formation of  $NH_3$ - $H_2SO_4$  clusters is the sufficiently low abundance of compounds competing with  $NH_3$  in forming clusters with  $H_2SO_4$ . One such class of compounds has been shown to be amines, in particular dimethylamine (Bzdek et al., 2011; Almeida et al., 2013). The measurements in the boreal forest have shown that large  $NH_3$ - $H_2SO_4$  clusters do not usually contain any amines. This observation suggests relatively low amine concentrations at the boreal forest measurement site in Hyytiälä (Schobesberger et al., 2013a). In fact, the prevalence of  $NH_3$  over amines is similar to the observations in the CLOUD chamber at the presence of contaminant levels of amines, indicating ambient amine concentrations in the boreal forest of <1 pptv.

It remains unsolved what is the exact role of  $NH_3$ - $H_2SO_4$  clusters, and  $NH_3$  in general, in the initial steps of the boundary layer events of new particle formation and growth that are frequently observed in the Finnish boreal forest and elsewhere (Kulmala et al., 2004b). Such clusters have been observed, but laboratory experiments suggest that they are not stable enough to fully account for the bulk of boundary layer particle formation (Kirkby et al., 2011). Other experiments conclude that clusters of two to three  $H_2SO_4$  molecules plus a mix of basic molecules ( $NH_3$  and amines) can in fact account for particle formation in polluted conditions (Chen et al., 2012).

Interactive Discussion

At least in clean environments rich in  $\alpha$ -pinene, such as boreal forests, recent experimental evidence hints at an important role of highly-oxidized organic compounds with extremely low volatility already in the first steps of boundary layer particle formation (Kulmala et al., 1998; Schobesberger et al., 2013a; Ehn et al., 2014; Riccobono 5 et al., 2014). These organic compounds probably feature several functional groups that facilitate hydrogen bonds with each other and with H<sub>2</sub>SO<sub>4</sub> molecules, in the same way as the bonds between H<sub>2</sub>SO<sub>4</sub> and NH<sub>3</sub> (Donahue et al., 2013). However, the inclusion of dimethylamine in these sub-2 nm clusters has been observed as well (Riccobono et al., 2014). Our ambient observations in the boreal forest suggest that a large fraction of H<sub>2</sub>SO<sub>4</sub> molecules in sub-2 nm clusters are found in clusters with NH<sub>3</sub>. Therefore, it is very likely that mixed sub-2 nm NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub>-organics clusters are also stable and indeed commonly contributing to particle formation in the boreal forest.

The measurement results presented here substantially extend our knowledge on how NH<sub>3</sub> and H<sub>2</sub>SO<sub>4</sub> interact in detail when forming and growing clusters under atmospheric conditions. The results are in general agreement with results from model simulations (e.g., Olenius et al., 2013a), as well as with previous experimental work (e.g., Bzdek et al., 2011, 2013; Froyd and Lovejoy, 2012). Altogether, we are moving closer to gaining a more complete and detailed understanding of this subject. The most important contribution of the present study is a detailed examination of cluster compositions under a wide range of atmospherically relevant conditions, and experimentally covering the whole sub-2 nm size range. Supported by simulations of cluster population dynamics, the results also allow for inferences to be made on electrically neutral NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> clusters.

Figure 2. Summary of a typical new particle formation experiment in the CLOUD chamber dur-

ing the CLOUD 2 campaign, with no added NH $_3$ , at 20 °C, 60 % relative humidity,  $3.7 \times 10^8$  cm $^{-3}$ 

 $[H_2SO_4]$ , 4 pptv  $[NH_3]$ , <1 pptv  $[C_2H_7N]$ , pion beam on. (A) Measurements of sulfuric acid con-

centration ([H<sub>2</sub>SO<sub>4</sub>]) by CIMS, showing the marked increase in [H<sub>2</sub>SO<sub>4</sub>] after the start of UV illumination. (B) Consequent new particle formation event as observed by the NAIS negative ion channel, showing negatively charged ions that grow from originally well below 2 nm to larger

sizes. The black box marks the time period of steady new particle formation that was used for

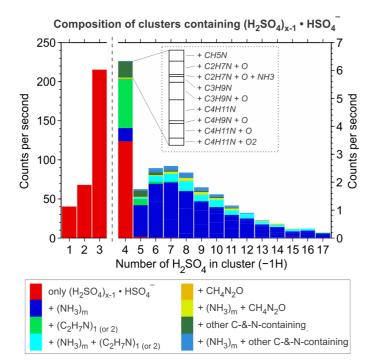

averaging APi-TOF data, and the size range covered by the APi-TOF mass spectra. (C) Mass

defect diagram for the APi-TOF mass spectrum, averaged over the shown particle formation

event. The diagram reveals the composition of the growing negatively charged ions between

about 1-2 nm. These are ion clusters, growing by the addition of H<sub>2</sub>SO<sub>4</sub> and contaminant NH<sub>3</sub> molecules (red and blue). Some clusters also contain contaminant amines (green and light

blue).

**Figure 3.** Details on the composition of the growing negatively charged clusters during the new particle formation experiment presented in Fig. 2, binned by the number x of  $H_2SO_4$  molecules in the cluster. Note that only ion clusters based on the  $HSO_4^-$  ion are shown, for simplicity. However, these ions constitute the majority of all ions, and practically all ions at x > 3 (i.e. beyond 350 Th, as can be seen in Fig. 2c). Besides contaminant  $NH_3$ , a wide range of contaminant nitrogen-containing organic compounds are seen in these clusters if x > 3, especially for x = 4. By far the most observed of these compounds is  $C_2H_7N$  (dimethylamine or ethylamine). Most likely all these organics are amines or amides (such as  $CH_4N_2O$ , probably urea), their high proton affinities facilitating the formation of clusters with  $H_2SO_4$ .

**Figure 4.** Number of gained NH<sub>3</sub> molecules per gained H<sub>2</sub>SO<sub>4</sub> molecule,  $\Delta m/\Delta n$ , plotted against the ratio of NH<sub>3</sub> and H<sub>2</sub>SO<sub>4</sub> gas-phase concentrations, [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>], for particle formation experiments at 19 to 20 °C, showing a positive correlation. Circles are for anion clusters (NH<sub>3</sub>)<sub>m</sub>·(H<sub>2</sub>SO<sub>4</sub>)<sub>n</sub>·HSO<sub>4</sub> and experiments at a relative humidity (RH) of 37 to 40 %. Colored squares denote experiments at lower RH (30 %) or higher RH (>59 %). Red plusses show  $\Delta m/\Delta n$  for cation clusters (NH<sub>3</sub>)<sub>m</sub>·(H<sub>2</sub>SO<sub>4</sub>)<sub>n</sub>·NH<sub>4</sub>, which are only observed at sufficiently high [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>], as marked by the shaded area, at an RH of 39 to 40 %. Values for  $\Delta m/\Delta n$  were determined for anion clusters in the range  $4 \le n \le 18^*$ , and for cation clusters in the range  $1 \le n \le 17^*$ . The lower limits of these ranges correspond to the sizes, from which onward  $\Delta m/\Delta n$  were constant. The upper limits were chosen, because up to these sizes a good signal was obtained for most experiments.

**Figure 5.** The composition of anion clusters,  $(NH_3)_m \cdot (H_2SO_4)_n \cdot HSO_4^-$ , during new particle formation experiments in the CLOUD chamber, shown as circles. RH was in the range 37–41 %, temperature is given by the color scale. (**A**) Number of gained NH<sub>3</sub> molecules per gained H<sub>2</sub>SO<sub>4</sub> molecule,  $\Delta m/\Delta n$ , plotted against the ratio of NH<sub>3</sub> and H<sub>2</sub>SO<sub>4</sub> gas-phase concentrations,  $[NH_3]/[H_2SO_4]$ .  $\Delta m/\Delta n$  for anion clusters was calculated for the range  $4 \le n \le 18^*$  for the results from the CLOUD 2 and 3 campaigns, and for the range  $4 \le n \le 9$  for the single result from CLOUD 5. Also shown are  $\Delta m/\Delta n$  for cation clusters  $(NH_3)_m \cdot (H_2SO_4)_n \cdot NH_4^+$  (for the range  $1 \le n \le 17^*$ ), which are observed only at sufficiently high  $[NH_3]/[H_2SO_4]$ . The green box and diamond markers show the corresponding results from ambient observations in the boreal forest. These are for  $(NH_3)_m \cdot (H_2SO_4)_n \cdot HSO_4^-$ ,  $4 \le n \le 8^*$ , observed during new particle formation in Hyytiälä in spring 2011. RH varied from 36 to 61 %, temperature from -0.5 to +8.5 °C. Dashed lines are ACDC model calculations of  $\Delta m/\Delta n$  for neutral clusters  $(NH_3)_m \cdot (H_2SO_4)_n \cdot HSO_4^-$ , calculated for the same ranges of *n* as in panel (**A**), and again plotted against  $[NH_3]/[H_2SO_4]$ . The legends in panel (**A**) apply to panel (**B**) as well.

\* Actual upper limits varied depending on obtained signals. For anion clusters in the CLOUD 2 and 3 campaigns, median( $n_{\text{max}}$ ) = 16.5; for cation clusters, median( $n_{\text{max}}$ ) = 17; for anion clusters in Hyytiälä, median( $n_{\text{max}}$ ) = 7.

Discussion Paper

**Figure 6.** Summary of the observed composition of  $(NH_3)_m \cdot (H_2SO_4)_n \cdot HSO_4^-$  anion clusters for the covered experimental conditions: varying vapor concentration ratios [NH<sub>3</sub>]/[H<sub>2</sub>SO<sub>4</sub>] (left vertical axis) and temperatures (horizontal axis and same color scale as for Fig. 5). Three specific features of cluster composition are presented at three investigated temperatures each, by a total of nine circles. These three features are (1) a fraction of 50 % of pure, NH<sub>3</sub>-free sulfuric acid clusters, (2) a ratio of added NH<sub>3</sub> molecules per added H<sub>2</sub>SO<sub>4</sub> molecule,  $\Delta m/\Delta n$ , = 0.5, and (3)  $\Delta m/\Delta n = 1$ . Values and uncertainties are based on the data shown in Fig. 5. Consequently, the grey shaded area at the bottom covers conditions allowing the formation of pure binary (NH<sub>3</sub>-free) H<sub>2</sub>O-H<sub>2</sub>SO<sub>4</sub> clusters. The grey shaded area at the top covers conditions that allow for the formation of clusters with about equal numbers of NH3 and H2SO4 molecules (as in ammonium bisulfate). The position of the green box and the color of its dashed edge line mark the conditions during the measurements in the boreal forest (Hyytiälä). Shown in brown (right vertical axis and line) is the ratio of saturation vapor pressures of NH3 and H2SO4  $(p_{\text{sat.NH}_2}/p_{\text{sat.H}_2\text{SO}_4})$ .

Interactive Discussion

Figure 7. Mass defect diagrams of ion mass spectra during new particle formation. The NH<sub>3</sub>-H<sub>2</sub>SO<sub>4</sub> ion clusters are colored, other ions are shown in grey. The colors reflect the relative numbers of acids and bases in the cluster, counting NH<sub>3</sub>, HSO<sub>4</sub>, HSO<sub>5</sub> and SO<sub>5</sub> as bases, and  $H_2SO_4$  as acid, and not counting  $NH_4^+$ . (A) Positively charged clusters  $(NH_3)_m \cdot (H_2SO_4)_n \cdot NH_4^+$ during new particle formation at CLOUD at  $[NH_3]/[H_2SO_4] = 185$ , temperature (T) = 19°C. Other ions (in grey) are mostly organic, N-containing contaminants, such as pyridine, charged by protonation. (B) Negatively charged clusters  $(NH_3)_m \cdot (H_2SO_4)_n \cdot HSO_4^-$  and  $(NH_3)_m \cdot (H_2SO_4)_n \cdot HSO_5^-$  during new particle formation at CLOUD at  $[NH_3]/[H_2SO_4] = 118$ ,  $T = 19 \,^{\circ}$ C. (C) Negatively charged clusters (NH<sub>3</sub>)<sub>m</sub>·(H<sub>2</sub>SO<sub>4</sub>)<sub>n</sub>·HSO<sub>4</sub> during a new particle formation event in the boreal forest, Hyytiälä, at  $[NH_3]/[H_2SO_4] = 485$ , T = 1 to 5 °C. Most of the signal of other ions (in grey) has a more positive mass defect and likely arises from ions containing mainly a variety of oxidized organics.
