# Abstract

The future heavy-ion experiment CBM (FAIR/GSI, Darmstadt, Germany) will focus on the measurements of very rare probes, which require the experiment to operate under extreme interaction rates of up to 10 MHz. Due to high multiplicity of charged particles in heavy-ion collisions, this will lead to the data rates of up to 1 TB/s. In order to meet the modern achievable archival rate, this data flow has to be reduced online by more than two orders of magnitude.

The rare observables are featured with complicated trigger signatures and require full event topology reconstruction to be performed online. The huge data rates together with the absence of simple hardware triggers make traditional latency-limited trigger architectures typical for conventional experiments inapplicable for the case of CBM. Instead, CBM will employ a novel data acquisition concept with autonomous, self-triggered front-end electronics.

While in conventional experiments with event-by-event processing the association of detector hits with corresponding physical event is known *a priori*, it is not true for the CBM experiment, where the reconstruction algorithms should be modified in order to process non-event-associated data. At the highest interaction rates the time difference between hits belonging to the same collision will be larger than the average time difference between two consecutive collisions. Thus, events will overlap in time. Due to a possible overlap of events one needs to analyze time-slices rather than isolated events.

The time-stamped data will be shipped and collected into a readout buffer in a form of a time-slice of a certain length. The time-slice data will be delivered to a large computer farm, where the archival decision will be obtained after performing online reconstruction. In this case association of hit information with physical events must be performed in software and requires full online event

reconstruction not only in space, but also in time, so-called 4-dimensional (4D) track reconstruction.

Within the scope of this work the 4D track finder algorithm for online reconstruction has been developed. The 4D CA track finder is able to reproduce performance and speed of the traditional event-based algorithm.

The 4D CA track finder is both vectorized (using SIMD instructions) and parallelized (between CPU cores). The algorithm shows strong scalability on many-core systems. The speed-up factor of 10.1 has been achieved on a CPU with 10 hyper-threaded physical cores.

The 4D CA track finder algorithm is ready for the time-slice-based reconstruction in the CBM experiment.

# Kurzfassung

Eines der Ziele des künftigen Schwerionenexperiments CBM (FAIR, Darmstadt, Deutschland) ist es, sehr seltene Teilchen zu messen, die mit extremen Kollisionsraten von bis zu 10 MHz erzeugt werden. Diese hohe Rate und die Multiplizität der geladenen Teilchen in Schwerionenkollisionen werden zu Datenraten von bis zu 1 TB/s führen. Um zu verarbeitbaren Archivierungsraten zu gelangen, muss der Datenfluss online um mehr als zwei Größenordnungen reduziert werden.

Einige der mit sehr niedrigen Wirkungsquerschnitten erzeugten Teilchen weisen komplizierte Zerfalltopologien auf, die eine vollständige Rekonstruktion der Ereignisse in Echtzeit erforderlich machen. Latenzbeschränkte Trigger-Architekturen, die typischerweise bei herkömmlichen Experimenten eingesetzt werden, können hier aufgrund der großen Datenraten und des Fehlens von einfachen Triggersignaturen nicht eingesetzt werden. Stattdessen wird im CBM-Experiment ein Datenerfassungskonzept mit autonomer, selbst-auslösender Front-End-Elektronik zum Einsatz kommen.

Während bei herkömmlichen Experimenten die Zuordnung von Detektor-Treffern einem physikalischen Ereignis entspricht, das über einen Trigger definiert wird, werden bei CBM die Detektortreffer mit einer Zeitmarke versehen und ausgelesen, ohne dass a priori bekannt ist, zu welchem Ereignis sie gehören. Die Rekonstruktionsalgorithmen müssen dahingehend modifiziert werden, dass nicht ereignisbasierte Daten verarbeitet werden können. Bei den höchsten Kollisionsraten wird die Zeitdifferenz zwischen Treffern derselben Kollision größer sein als die durchschnittliche Zeitdifferenz zwei aufeinanderfolgender Kollisionen. Somit werden die Ereignisse zeitlich überlappen. Aufgrund dieser Situation erfolgt die Analyse auf "Zeitschnitten". Ein Zeitschnitt umfasst dabei Daten, die innerhalb eines Zeitintervalls registriert wurden. Die Daten werden mit einer Zeitmarke versehen, an einen Auslesepuffer in Form eines Zeitschnitts einer bestimmten Dauer geschickt und dort gespeichert. Die Zeitschnittdaten werden an eine große Computerfarm weitergeleitet, wobei die Archivierungsentscheidung nach dem Durchführen der Online-Rekonstruktion erhalten wird. In diesem Fall muss die Zuordnung von Trefferinformation zu physikalischen Ereignissen mithilfe der Software durchgeführt werden. Dieses erfordert eine vollständige Online-

Ereignisrekonstruktion nicht nur im Raum, sondern auch in der Zeit, d.h. eine vierdimensionale (4D) Spurrekonstruktion.

Im Rahmen dieser Arbeit ist der 4D-Spurfinder-Algorithmus für Echtzeitrekonstruktion entwickelt worden. Der 4D-Spurfinder, der auf dem zellulären Automaten (Cellular Automaton, CA) basiert, ist in der Lage, die Performanz und die Geschwindigkeit des ereignisbasierten Algorithmus zu reproduzieren.

Der 4D-CA-Spurfinder ist sowohl vektorisiert (mittels SIMD-Befehlen) und parallelisiert (zwischen CPU-Kernen). Der Algorithmus zeigt starke Skalierbarkeit auf Mehrkern-Systemen. Ein Beschleunigungsfaktor von 10,1 wurde mit Hyper-Threading auf zehn physischen Kernen einer CPU erreicht.

Der 4D-CA-Spurfinder-Algorithmus ist für zeitschnittbasierte Rekonstruktion für das CBM Experiment ausgearbeitet worden.

# Chapter 1

## Introduction

In the last decades significant experimental and theoretical efforts worldwide have been devoted to the investigation of the properties of nuclear matter under conditions, which are far from normal ones. A wide range of experiments, including CBM<sup>1</sup> [1] at FAIR<sup>2</sup>, ALICE<sup>3</sup> [2] at CERN<sup>4</sup>, STAR<sup>5</sup> [3] and PHENIX<sup>6</sup> [4] at RHIC<sup>7</sup> are committed to exploring this topic. Heavy-ion collision experiments provide a unique opportunity for creating hot and dense nuclear matter, which can be investigated experimentally. The mission of these experiments, which are performed worldwide, is to study the structure and the properties of strongly-interacting matter under extreme conditions by exploring the phase diagram of matter governed by the laws of Quantum-Chromo-Dynamics (QCD). In the heavy-ion experiments, collisions generate extremely hot and dense matter, thus recreating conditions similar to those ones, that existed during the first few microseconds after the Big Bang. Such conditions may still exist in nature, in the interior of neutron stars, for example.

The CBM experiment at the future FAIR facility in GSI<sup>8</sup> is designed to run at unprecedented in heavy-ion experiments interaction rates of up to 10 MHz.

Therefore, it will play a unique role in exploring the QCD phase diagram in the region of densities close to the neutron star core density. High-rate operation is the key requirement necessary in order to measure with high precision and statistics rare diagnostic probes, which are sensitive to the dense phase of nuclear matter. Such probes are multi-strange hyperons, lepton pairs, and particles containing charm quarks. Their signatures are complex. This implies a novel read-out and data acquisition concept with self-triggered front-end electronics and free-streaming data. The data analysis must be performed in software online, and requires four-dimensional reconstruction routines. This thesis is devoted in particular to the development of the time-based tracking algorithm for online and offline data processing in the CBM experiment.

## 1.1 Strongly interacting matter under extreme conditions

It is a great challenge to understand the processes, which may have led to the creation of the physical world as we know it. How did the Universe begin? Throughout time these fundamental question of our existence has occupied the minds of scientists all over the world. Modern physics has provided some theories, but a majority of these answers have only led to more intriguing and more complex questions and most of our assumptions are still only hypotheses. Our current understanding of the Big Bang, the first atoms and the structure of matter is obviously incomplete.

The Big Bang, the prevailing cosmological theory for the origin and the earliest periods of the Universe evolution, states that our Universe was born in a massive explosion, and was gradually cooling down from the initial state of extreme energy densities and temperatures. Thus, the formation of baryonic matter, which is the building blocks of matter and life as we know it, occurred as a result of the Universe expansion. According to the theory in this explosion matter must have gone through phases, not observed under normal conditions, like Quark-Gluon Plasma (QGP) [5, 6, 7]. In nature matter in the QGP phase may still exist in the interior of compact stellar objects.

One of the ways to study baryonic genesis and the structure of matter in the laboratory is by means of high-energy heavy-ion collisions. For this purpose, heavy nuclei like those of lead and gold, are collided with the highest energies so that they form an intermediate hot and dense state, the so-called fireball.

The evolution of the Universe from the Big Bang into what it is today must have been determined by the fundamental laws of physics that govern the smallest elementary particles, namely quarks, leptons, and force carrying bosons like gluons, existing in extremely small regions at huge energies. These conditions are well beyond the levels of energies generated by high-energy physics (HEP) experiments in modern accelerators. Thus, we need to look deeply into the structure of matter to understand thoroughly its elementary constituents and the fundamental forces acting upon them, in order to explain the origins and the structure of matter and the Universe.

## 1.2 The phase diagram of strongly interacting matter

Under normal conditions, at nuclear matter ground state density and low temperatures, nuclear matter exists in the form of protons and neutrons, each containing three color-charged valence quarks, plus a sea of virtual quark-antiquark pairs and color-charged gluons. These color-charged particles (quarks and gluons) cannot be found individually, but only confined with other color-charged particles into a color neutral groups (hadrons). This property is called *color confinement*.

The nuclear density typically found in nuclei is less than the density of a single nucleon ( $0.3 \text{ GeV}/\text{fm}^3$ ) and amounts to about  $0.15 \text{ GeV}/\text{fm}^3$  [8], indicating that the nucleons are well separated and do not overlap. If we start increasing compression, moving towards higher densities and more extreme conditions, at some point the volume available for a single nucleon gets smaller than the natural size of a nucleon leaving no possibility to distinguish different nucleons. In this case a single quark can no longer be associated with a certain nucleon, and, thus, is not confined any more inside the nucleon. A similar effect can be reached as the temperature increases: frequent collisions between the nucleons lead to

**Figure 1.1:** A scheme of the QCD phase diagram of strongly interacting matter [9].

the fact that quarks are not confined to a certain group. This new state of matter consisting of unbound quarks and gluons is called QGP. It is generally believed that the early Universe went through a phase like QGP, where the high temperature prevented the formation of hadrons from the initial soup of quarks and gluons.

The modern predictions on the phase diagram of strongly interacting matter are sketched in Fig. 1.1 in terms of thermodynamical parameters temperature ( $T$ ) and net baryon density ( $n_B$ ), which characterizes the difference between particles and antiparticles in the system. It includes conjectures which are not fully established. In general normal conditions correspond to the region of low  $T$  and  $n_B$  in the diagram, where quarks and gluons are bound into colorless objects — hadrons. The QGP phase is expected to occur at higher  $T$  or/and  $n_B$ .

The major method used to obtain theoretical predictions for the QCD phase diagram are lattice QCD calculations [10], which relate the fundamental interactions between quarks and gluons with thermodynamical properties of the QGP,

such as energy density and temperature. In the region of low net baryon densities and high temperatures, lattice QCD calculations predict a smooth crossover from normal hadronic to deconfined matter [11]. The transition temperature, corresponding to this crossover, is estimated between 155 and 165 MeV [12, 13, 14].

At a finite net baryon density, standard numerical lattice simulations do not work well and still need some modification in order to produce firm predictions. Therefore our knowledge of the QCD phase diagram at nonzero  $n_B$  relies exclusively on effective models. At large net baryon density these model calculations predict a first order transition between hadronic matter and deconfined QGP [15, 16, 17] instead of the crossover, which means that both of these two phases are present: the areas of hadron gas coexist with the areas filled with QGP. It is predicted that crossover and first order transition are denoted with critical endpoint [15], where strong fluctuations of the physical parameters are expected.

Another possible phase transition in the QCD diagram apart from deconfinement is the chiral phase transition. This *chiral symmetry* is a symmetry of the QCD Lagrangian in the limit of vanishing quark masses. If a quark has a zero mass, then the spin of the quark can either be in the direction of motion (a right-handed quark), or in the opposite direction (a left-handed quark). Since a massless quark travels at the speed of light, the handedness or *chirality* of the quark is independent of any Lorentz frame, from which the observation is made.

This symmetry was found to be spontaneously broken in nature since the quark masses are finite. However, compared with hadronic scales the masses of the two lightest quarks, up and down, are very small, so that, at low energies, the chiral symmetry may be considered an approximate symmetry of the strong interactions. It is theoretically predicted that at high temperature or net baryon density the spontaneously broken chiral symmetry is restored.

The chiral phase transition is a transition from chirally symmetric matter at high temperatures and net baryon densities to the state with broken chiral symmetry. Chiral and deconfinement phase transitions are not necessarily equivalent. A better understanding of chiral phase transition via studying the matter under extreme conditions, can explain the mechanisms of the origin of hadron masses: why a hadron, that is composed of light quarks, is much heavier than the sum of

the masses of its constituents?

Moreover, there are models which predict new phases such as quarkonic phase [18] and the color superconductor [19, 20] .

The experimental discovery of any of the above mentioned prominent landmarks and regions of the QCD phase diagram would be a major breakthrough in our understanding of the properties of nuclear matter.

### 1.3 Probing strongly interacting matter with heavy-ion collisions

Experimentally, strongly interacting matter under extreme conditions is produced and studied in high-energy heavy-ion collision experiments. Different experiments worldwide are aiming to cover different regions of the QCD phase diagram in order to get a complete scan of the diagram.

The experiments at the LHC and at top energies of RHIC and SPS<sup>9</sup> cover in their studies the diagram region with very high energy density and equal numbers of particles and antiparticles, i.e. vanishing net baryon densities. This region corresponds to conditions close to matter of the early Universe about 10  $\mu$ s after the Big Bang [21].

On the other hand, the region of small temperatures at large net baryon densities corresponds to the interior of compact stellar objects like neutron stars [22, 23]. Several experimental programs are devoted to the exploration of the high net baryon density region. The STAR and PHENIX experiments at RHIC aim to scan the beam energies, and to search for the QCD critical endpoint. For the same reason, measurements are performed at CERN-SPS with the upgraded NA61 detector. At the JINR<sup>10</sup> a heavy-ion collider project NICA<sup>11</sup> [24] is planned with the goal of searching for the coexistence phase of nuclear matter.

However, not only beam energy is important in order to investigate dense matter. The beam luminosity and data taking rate available for a certain detector play an important role, defining the sort of measurements available for a certain

---

<sup>9</sup>Super Proton Synchrotron

<sup>10</sup>Joint Institute for Nuclear Research, Russia

<sup>11</sup>Nuclotron-based Ion Collider fAcility

experiment. The measurements, which possibly can be made by experiments, are, for instance, the bulk observables and the rare probes.

The freeze-out phase, when no new particles can be produced in the collisions, can be studied with measurement of “soft” hadrons production (bulk observables). The term “bulk” denotes the fact that they directly characterize the medium produced in the collision.

By contrast, the information of the earlier phases is carried by rare probes, namely particles built up of heavy quarks ( $\Lambda, \Sigma, \Xi, \Omega, J/\Psi, D \dots$ ). Moreover, in order to obtain information on the early and dense phase of the fireball evolution, one has to measure, for example, multi-differential observables such as the flows of identified particles as a function of the transverse momentum ( $p_t = \sqrt{p_x^2 + p_y^2}$ ) of the particles, mass distributions of dileptons and particles containing heavy quarks as a function of  $p_t$ . These measurements require high reaction rates, fast detection and a high-speed data acquisition system.

While every heavy-ion experiment is suited to measure bulk observables, the sensible use of rare probes requires high luminosity beams as well as detectors capable of high rate data taking. The collider experiments are typically limited due to their beam luminosity, while the fixed target experiments have the opportunity to get significantly higher statistics due to higher reaction rates. In case of fixed target experiments the reaction rate is mainly limited by the detector capabilities. Thus, the collider experiments are often constrained to the measurements of bulk observables, due to lower statistics in case of high precision measurements of rare probes.

In contrast, the research program of the CBM experiment at FAIR is focused on the measurement of both bulk and rare probes with unprecedented statistics. A combination of high-intensity beams with a high-rate detector system is planned to be used in order to meet this goal.

# Chapter 2

## The Compressed Baryonic Matter (CBM) experiment

### 2.1 CBM at the Facility for Antiproton and Ion Research (FAIR)

This chapter is devoted to the physics goals and the detector setup together with the novel data acquisition and event selection systems of the CBM experiment.

FAIR [25] is a new accelerator facility, situated at the GSI Helmholtz Centre for Heavy Ion Research in Darmstadt, Germany. It will deliver high intensity beams of ions ( $10^9$  particles/s for Au-ions) and antiprotons ( $10^{13}$  particles/s) for experiments in the fields of nuclear, hadron, atomic and plasma physics.

The layout of the future FAIR complex together with existing GSI facilities is illustrated in Fig. 2.1. The core of the facility will be two large synchrotrons with rigidities of 100 Tm and 300 Tm (SIS100 and SIS300, where SIS stands for SchwerIonenSynchrotron). One of the scientific pillars of FAIR is the CBM experiment aiming at exploration of the QCD phase diagram at high baryon densities. The start version of the CBM setup is designed for ambitious nuclear-matter research program using beams from SIS100. The experiment program will be extended towards higher beam energies with the full version of the CBM detector system using high-intensity beams from SIS300.

**Figure 2.1:** Layout of the FAIR facility (left side) [25]. The new facility and the existing GSI complex are shown in red and grey, respectively. Aerial photo of the construction site (right side) taken on April 22, 2015 [26]

## 2.2 The CBM physics cases and observables

CBM will investigate collisions of heavy ion and proton beams with fixed targets at beam energies from 2 to 45 AGeV (GeV per nucleon). The CBM research program aims to study the structure and the equation-of-state of baryonic matter at densities comparable with the density of the inner core of neutron stars.

The research program is focused on [1]:

- the study of the equation-of-state of nuclear matter at neutron star densities
- the search for the phase boundary between hadronic phase and quark-gluon matter, or a region of phase coexistence, and the QCD critical endpoint
- the search for modifications of hadron properties in the dense baryonic matter and signatures for chiral symmetry restoration
- the search for single and double hypernuclei, heavy multi-strange objects
- the investigation of the production mechanism of charm quarks at threshold beam energies and the charm propagation in nuclear matter

The experimental and theoretical challenge is to study observables, which address the physics cases mentioned above. The observables are the yields and phase-space distributions of newly produced particles, their correlations and fluctuations.

**Figure 2.2:** Particle multiplicities times branching ratio for central Au+Au collisions at 25 AGeV calculated with the HSD transport code [27] and the statistical model [28].

Large beam intensity combined with very high reaction rates results in the unprecedented statistical significance for the particles with extremely low production cross sections. Hence, the CBM detector system is designed to measure both bulk observables with large acceptance as well as rare diagnostic probes.

Having this unique feature, the CBM experiment is aiming to measure a wide range of particles with predicted multiplicities varying over many orders of magnitude: starting from the abundant pions up to the rare charmonium states. In Fig. 2.2 the prediction of particle multiplicities times branching ratio of the measurable particles calculated with the Hadron-String Dynamics (HSD) transport model or the statistical model for central Au+Au collisions at 25 AGeV are plotted. Data points below the dashed line correspond to particles that up to now have not been measured by any experiment at this beam energy. The CBM collaboration plans to measure all these particles. Different particle species probe different phases of the fireball evolution depending on their production and interaction cross sections, decay channels and lifetime.

FAIR will provide heavy-ion beam energies from 2–11 (14) AGeV for  $Q=0.4$  A (0.5 A) nuclei with the SIS100 synchrotron, and 11–35 (45) AGeV with the SIS300 synchrotron. According to transport model calculations, already in central

Au+Au collisions at top SIS100 energies the nuclear fireball will be compressed to more than 8 times normal nuclear density  $\rho_0$  [29]. Such conditions prevail in core collapse supernovae and in the core of neutron stars [30].

Measurements at FAIR energies will focus on the investigation of the properties of resonance matter in the vicinity of the phase boundary, and, therefore, will provide important information on this transition region of the QCD phase diagram. The heavy-ion beams at FAIR are well suited for the search of the most prominent landmarks of the QCD phase diagram at high net baryon densities: the first order deconfinement and/or chiral phase transition. Moreover, the research program includes the study of the equation-of-state of high-density baryonic matter, and the search for modifications of hadronic properties in the dense baryonic medium as signatories for chiral symmetry restoration.

Let us briefly discuss the physics cases and the relevant measurements, which the CBM research program is focused on [31, 32].

**The equation-of-state of baryonic matter at neutron star densities.**

The determination of the equation-of-state (EOS) is a major goal of the investigation of nuclear matter at high energy densities. Furthermore, these studies may provide a direct experimental signature of the anticipated phase transitions for deconfinement and chiral symmetry restoration.

The relevant measurements are:

- The *excitation function* (a function with respect to the collision energy in the center of mass frame) of the collective flow of hadrons;

*Collective flow* represents the azimuth anisotropy of the particle yields in the momentum space and gives valuable information on the space-time evolution of the fireball. The strength of elliptic flow, measured as a function of transverse momentum for different particle species, reflects the initial pressure of the system [33]. The vanishing of directed flow at a certain beam energy would indicate a strong *softening of the equation-of-state*, which means that the density becomes less sensitive to the change in the pressure.

- The excitation functions of multi-strange hyperon yields in Au+Au and C+C collisions at energies at 2 to 11 AGeV (SIS100).

The excitation function of strange hadron yields and phase space distributions (including multi-strange hyperons) will provide information about the fireball dynamics and the nuclear matter equation-of-state over a wide range of baryon densities. At sub-threshold energies,  $\Xi$  and  $\Omega$  hyperons are produced in sequential collisions involving kaon and  $\Lambda$  particles, and, therefore, are sensitive to the density in the fireball.

### **In-medium properties of hadrons.**

The restoration of chiral symmetry in dense baryonic matter will modify the properties of hadrons. The relevant measurements are:

- The in-medium mass distribution of vector mesons ( $\rho, \omega, \phi$ ) decaying in lepton pairs in heavy-ion collisions at different energies (2–45 AGeV), and for different collision systems (SIS100/300);

The measurement of short-lived vector mesons via their decay into an electron-positron pair provides a unique possibility for studying the properties of vector mesons in dense baryonic matter. The lepton pair is called a “penetrating probe” because it delivers undistorted information on the conditions inside the dense fireball. The invariant masses of the measured lepton pairs permit the reconstruction of the in-medium spectral function of the  $\rho, \omega, \phi$  mesons, if they decay inside the medium. Such data is expected to shed light on the fundamental question as to what extent chiral symmetry is restored at high baryon densities and how this affects the hadron masses [34].

- Yields and transverse mass ( $m_t = \sqrt{m^2 + p_x^2 + p_y^2}$ ) distributions of charmed mesons in heavy-ion collision as a function of collision energy (SIS100/300).

Particles containing heavy quarks, like charm, can be created in the hard processes at the early stage of fireball evolution exclusively, especially at the FAIR energies near the threshold for the charm-anticharm pair production.

The D-mesons, the bound states of a heavy charm quark and a light quark, are predicted to be modified in the nuclear medium [35]. To the extent that these modifications are partly related to in-medium changes of the light-quark condensate, they offer another interesting option to probe the restoration of chiral symmetry in dense hadronic matter [35].

Non-monotonic behavior of the inverse slope of the transverse momentum spectra as a function of the beam energy would signal a change in the nuclear matter properties at a certain net baryon density. The distribution of the inverse slope as a function of particle mass is related to the particle *freeze-out phase* (phase, when the collisions between particles cease), and, hence, may help to delineate the early from the late collision stages.

**Phase transitions from hadronic matter to quarkyonic or partonic matter at high net-baryon densities.**

A discontinuity or sudden variation in the excitation functions of sensitive observables would be indicative of a deconfinement transition. The relevant measurements are:

- The excitation function of yields, spectra, and collective flow of strange and charmed particles in heavy-ion collisions at 6–45 AGeV (SIS100/300);

The yields of rare particles containing strangeness and charm, in particular when produced at beam energies close to the corresponding threshold, depend on the conditions inside the early fireball [36].

Enhanced strangeness production was proposed as a possible signal for the QGP formation [37]. In the parton-parton interaction scenarios strange quarks are expected to be produced more abundantly than in hadronic reaction scenarios. As a result, the yields of strange particles, scaled by the number of participating nucleons, are expected to be higher in heavy-ion collisions with creation of a QGP than in p+p interactions.

The idea is that the production of strange quark pairs is energetically favored in the quark-gluon plasma as compared to hadronic matter. The enhancement is expected to be most pronounced for particles containing two or even three strange quarks such as  $\Xi$  and  $\Omega$ .

- The excitation function of yields and spectra of lepton pairs in heavy-ion collisions at 6–45 AGeV (SIS100/300);

The slope of the dilepton invariant mass distribution between 1 and 2 GeV/ $c^2$  directly reflects the average temperature of the fireball. The study of the energy dependence of this slope opens a unique possibility of measuring the caloric curve

which would be a signature for phase coexistence [38]. This measurement would also provide indications for the onset of deconfinement and the location of the critical endpoint.

- Event-by-event fluctuations of conserved quantities like baryon, strange and net-charge etc. in heavy-ion collisions with high precision as a function of beam energy at 6–45 AGeV (SIS100/300).

The presence of a phase coexistence region is expected to cause strong fluctuations from event to event in the charged particle number, baryon number, strangeness-to-pion ratio, average transverse momentum, etc. Similar effects are predicted to occur in the vicinity of the QCD critical point.

### **Hypernuclei, strange dibaryons and massive strange objects.**

Nuclei containing at least one hyperon in addition to nucleons offer the fascinating perspective of exploring the third, strange dimension of the chart of nuclei. Their investigation provides information on the hyperon-nucleon and on the hyperon-hyperon interaction in particular, which plays an important role in neutron star models.

Theoretical models predict that single and double hypernuclei, strange dibaryons and heavy multi-strange short-lived objects are produced via coalescence in heavy-ion collisions with a maximum yield in the region of SIS100 energies [39, 40]. The planned measurements include:

- The decay chains of single and double hypernuclei in heavy ion collisions at SIS100 energies;
- Search for strange matter in the form of strange dibaryons and heavy multi-strange short-lived objects. Whether or not these multi-strange particles decay into charged hadrons including hyperons, which can be identified via their decay products.

### **Charm production mechanisms, charm propagation, and in-medium properties of charmed particles in dense nuclear matter.**

Due to the large mass,  $cc$ -quark pairs can only be produced in the hard processes of the early stage of collision. The created charm quarks either propagate as charmonium (hidden charm) or pick up light quarks to form pairs of D-mesons

(open charm) or charmed baryons. The production and propagation of charm in heavy-ion collisions are expected to be a particularly sensitive probe of the hot and dense medium.

The majority of charmed quarks are carried away as open charm. During the evolution of the fireball, charm quarks undergo exchange of the momentum with the medium. The exchange process depends strongly on the properties of the medium. Therefore, momentum distributions, correlations, and elliptic flow of open charm hadrons is an important diagnostic probe of the prevailing degrees of freedom in the early collision stage.

Also, charmonium states are observables sensitive to the conditions in the fireball. The suppression of charmonium due to color screening is predicted as a signature for the quark-gluon plasma [35].

The free color charges in the deconfined phase are expected to screen the mutual attraction of the charmed quarks and hence prevent the formation of charmonium states. The relevant measurements are:

- Cross sections, momentum spectra, and collective flow of open charm (D-mesons) and charmonium in proton-nucleus and nucleus-nucleus collisions at SIS300 energies.

As discussed above, a substantial part of the CBM physics cases can already be addressed with beams from the SIS100 synchrotron. A general review of the physics of compressed baryonic matter, the theoretical concepts, the available experimental results, and predictions for relevant observables in future heavy-ion collision experiments can be found in the CBM Physics Book [1].

## 2.3 The experimental setup

The challenging CBM physics program requires a high performance detector system with two configurations: one version optimized for detection of electrons, the other — for muons.

In the electron configuration the following detectors will be used: Micro-vertex Detector (MVD), Silicon Tracking System (STS), both placed in a gap of 1 Tm

**Figure 2.3:** The CBM detector setup versions for electron (top) and muon registration (bottom). In the electron configuration the subdetectors are: Micro-vertex Detector (MVD), Silicon Tracking System (STS), both placed in a gap of 1 Tm superconducting magnet, then Ring Imaging Cherenkov Detector (RICH), Transition Radiation Detectors (TRD), Resistive Plate Chambers for time-of-flight measurements (TOF), Electromagnetic Calorimeter (ECAL) and Projectile Spectator Detector (PSD) as a hadronic calorimeter. In the muon configuration the RICH detector will be replaced by the Muon Chambers System (MUCH) and ECAL will be removed.

superconducting magnet, then Ring Imaging Cherenkov Detector (RICH), Transition Radiation Detectors (TRD), Resistive Plate Chambers for Time-Of-Flight measurements (TOF), Electromagnetic Calorimeter (ECAL) and Projectile Spectator Detector (PSD) as a forward hadronic calorimeter.

In the muon configuration the RICH detector will be replaced by the Muon

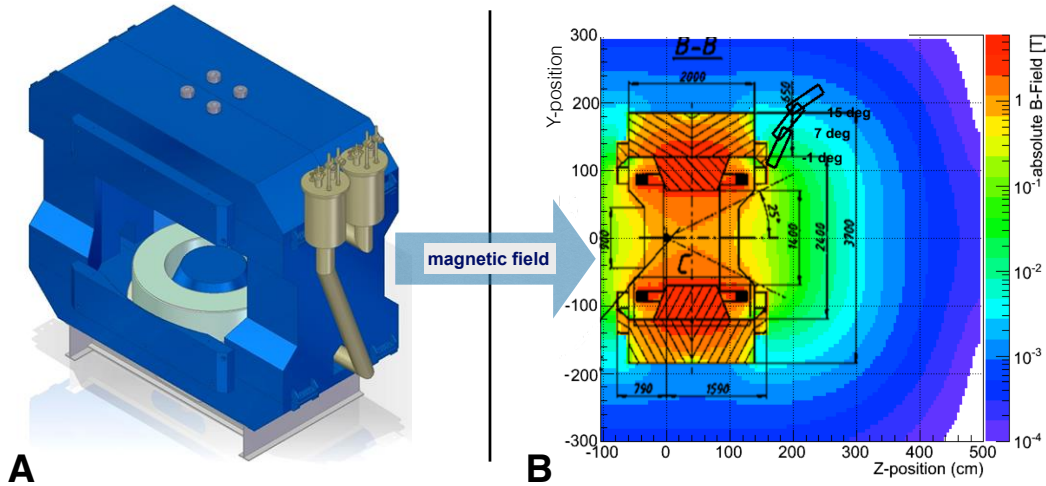

Chambers System (MUCH) and ECAL will be removed (Fig. 2.3).

Observables	MVD	STS	RICH	MuCh	TRD	TOF	ECAL	PSD
$\pi$ , K, p		X	(X)		(X)	X		X
Hyperons		X			(X)	(X)		X
Open charm	X	X	(X)		(X)	(X)		X
Electrons	X	X	X		X	X		X
Muons		X		X		(X)		X
Photons							X	X
Photons via $e^\pm$ conversions	X	X	X		X	X		X

**Table 2.1:** The CBM observables. The subdetectors required for a certain observable are marked as X. The subdetectors marked as (X) can be used optionally to suppress background.

The CBM subdetectors required for the measurement of the different observables are listed in Tab. 2.1. The system subdetectors are described in detail below.

### 2.3.1 The superconducting dipole magnet

**Figure 2.4:** (A) Geometry of the superconducting dipole magnet. (B) Magnetic field distribution in the  $Y$ - $Z$ -plane at  $X=0$  [41].

The superconducting dipole magnet [41] serves to bend charged particle trajectories in order to determine their momenta. The current geometry of the magnet is shown in Fig. 2.4(A).

It will provide bending power to the tracking detectors MVD and STS. It has a large aperture of  $\pm 25^\circ$  in polar angle and provides a magnetic field integral of 1 Tm for a sufficient momentum resolution. The magnet should be large enough to permit the installation and maintenance of the MVD and the STS, which implies that the size of magnet should be at least  $1.3 \times 1.3 \text{ m}^2$ .

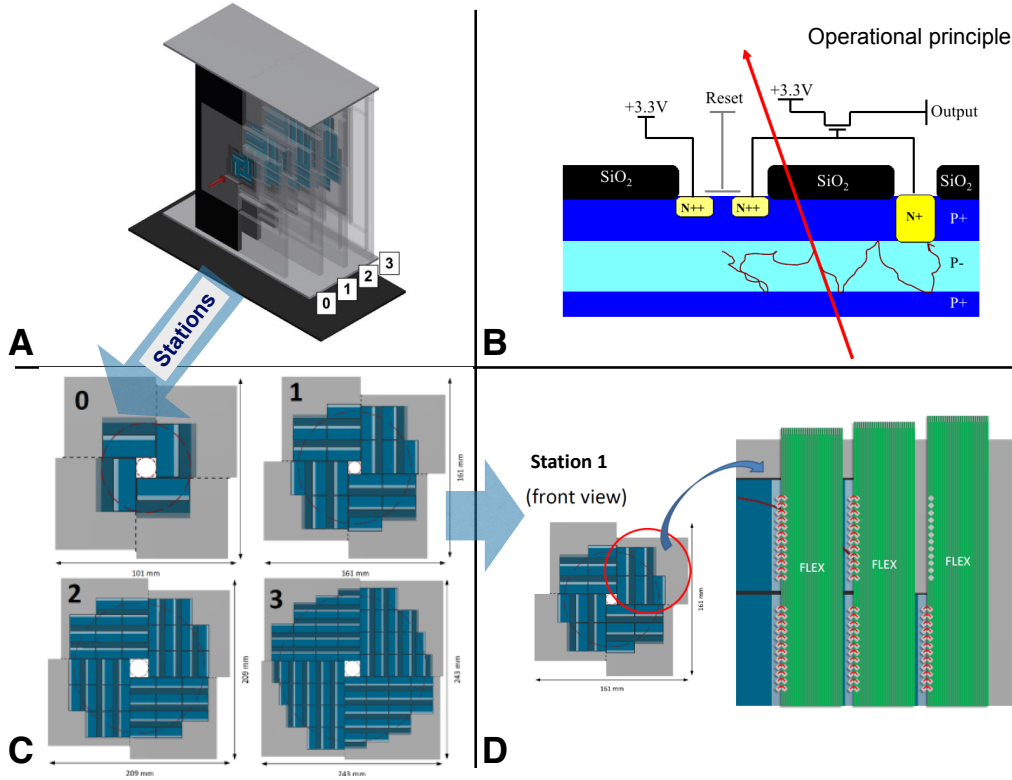

Since in order to meet the requirements the dipole magnet was chosen, the resulting magnetic field is non-homogeneous. The magnetic field distribution, calculated with ToSCA-program [42], for the current version of the magnet is shown in Fig. 2.4(B).

### 2.3.2 Micro-Vertex Detector (MVD)

The Micro-Vertex Detector [43] design is mainly driven by the goal of determining the position of a particle interaction or decay point (secondary vertex) by tracing the reaction products to their common point of origin. In order to achieve a high secondary vertex resolution, the MVD has to be located close to the target. The MVD consists of four layers of Monolithic Active Pixel Sensor (MAPS) (Fig. 2.5(A)) located from 5 cm to 20 cm downstream of the target in a vacuum.

The MAPS principle was originally developed as a digital camera image sensors. MAPS can be produced in a standard Complementary Metal-Oxide-Semiconductor (CMOS) process. It allows for the integration of sensor pixels as well as analog and digital signal processing circuitry on a single chip (for this reason it is called “monolithic”).

The sensitive component of the pixel is a reversed biased diode (see Fig. 2.5(B)), while the active volume of the sensor comprises the entire epitaxial layer, which has a typical thickness of 12–16  $\mu\text{m}$ . When a particle is traversing the chip, ionizing radiation produces electron-hole pairs. The sensing diodes collect the diffusing electrons and generate a charge signal. The charge signal is converted into a voltage signal by a dedicated Metal-Oxide-Semiconductor Field-Effect Transistor (MOSFET) inside the pixel (for this reason it is called “active

**Figure 2.5:** (A) The 3D view of the MVD model, depicting the sensors (C) and the mechanical holding structure including the layout of the stations. (B) Fundamental layout of a CMOS sensor pixel [44]. (D) The MVD front-end electronics including the flex print cables.

pixel”). The sensors are bonded to a custom-made flex print cable, which connects to the front-end board (Fig. 2.5(C)).

The detector arrangement provides a resolution of secondary vertices of about 50–100  $\mu\text{m}$  along the beam axis.

### 2.3.3 Silicon Tracking System (STS)

The Silicon Tracking System (STS) [31] is the main tracking detector of the CBM experiment. Thus, the task of the STS is to provide track reconstruction and momentum determination of charged particles. The multiplicity of charged particles is up to 700 per event within the detector acceptance. The required momentum resolution is of an order of  $\Delta p/p = 1\%$ . This resolution can only be achieved with an ultra-low material budget and particular restrictions on the location of power-dissipating front-end electronics in the fiducial volume.

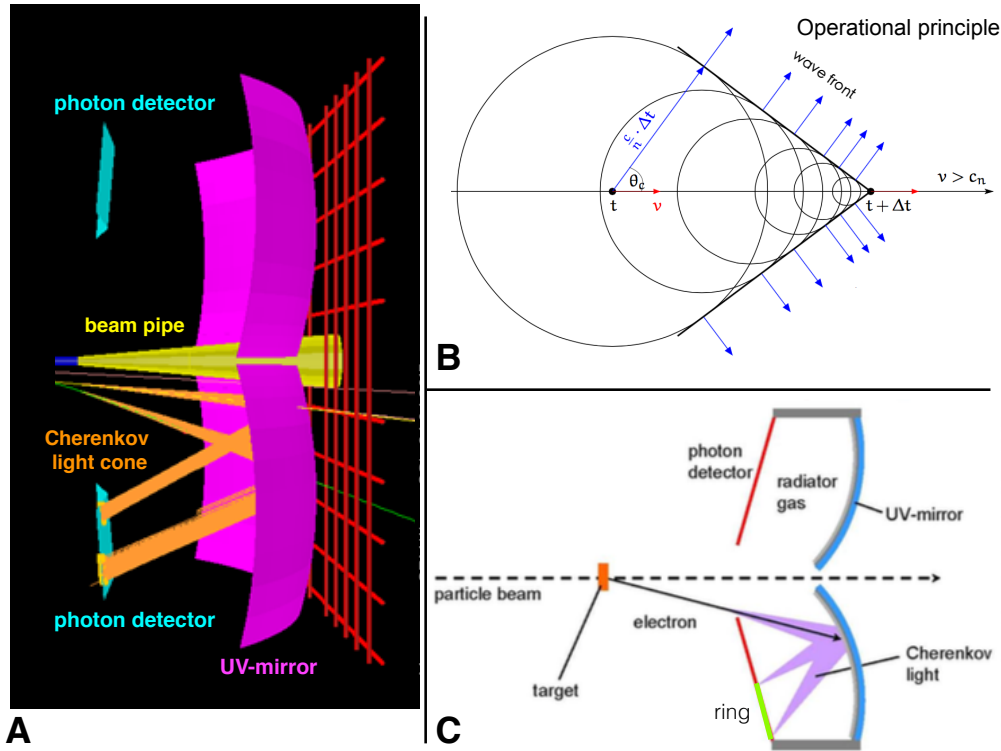

**Figure 2.6:** (A) The layout of the STS stations [31]. (B) The operational principle of the silicon strip detector [45]. (C) The layout of the 6th STS station. The color codes within the stations denote commonly read-out sensors. The circles indicate the acceptance between polar angles  $2.5^\circ$  and  $25^\circ$ .

The STS consists of 8 tracking layers of silicon detectors (see Fig. 2.6(A)). It is based on double-sided silicon micro-strip sensors with a stereo angle of  $7.5^\circ$  and a strip pitch of  $58 \mu\text{m}$ . The sensors are mounted onto lightweight support ladders, which will be read out through multi-line micro-cables with fast electronics at the periphery of the stations. The STS covers polar angles from  $2.5^\circ$  to  $25^\circ$ .

The system is located within a range of 30 cm to 100 cm from the target, keeping the spacing between stations at about 10 cm. It is placed inside the 1 m long gap of a superconducting dipole magnet providing the bending power required for momentum determination with a resolution of  $\Delta p/p = 1\%$ .

The principle of operation of the silicon microstrip detector is shown in Fig. 2.6(B). The sensitive component of the silicon detector is a reverse biased diode with the depleted zone acting as a solid-state ionization chamber. When

**Figure 2.7:** (A) The layout of the RICH stations [46]. (B) The principle of the Cherenkov radiation. The schematic view of the RICH detector with its imaging UV mirrors. (C) The Cherenkov-cones are imaged on the detectors as rings.

charged particles pass through an active volume of the detector, many electron-hole pairs are produced along the path of the particle. Under the application of reverse-bias, the electrons drift towards the n-side and holes to the p-side. This charge migration induces a current pulse on the read-out electrodes. The high mobility of electrons and holes allows for a very fast collection of the charge signal.

### 2.3.4 Ring Imaging Cherenkov detector (RICH)

The main task of the RICH detector [46] (Fig. 2.7(A)) is to select electrons and positrons, in particular to distinguish them from pions in the momentum range below  $10 \text{ GeV}/c$  with a pion suppression on the order of  $10^3$ – $10^4$ .

The operation principle of the RICH detector is based on the Cherenkov effect. The Cherenkov radiation is produced when a charged particle travels faster than

the speed of light in the medium, through which it passes. The particle excites atoms or molecules around it with the electromagnetic field and they fall back down to ground level by emitting Cherenkov photons. The emitted Cherenkov radiation travels at the speed of light in the medium, given by  $c/n$ , where  $c$  is the speed of light in a vacuum and  $n$  is the index of refraction. It results in the Cherenkov photons forming a cone-shaped front (Fig. 2.7(B)), whose half angle is greater for faster particles and media with higher refractive indexes. The radiation occurs mainly in the visible and UV region of the spectrum. Inside the detector this Cherenkov light cone is reflected by a focusing mirror to a position-sensitive photon detector, which allows reconstructing the produced rings (Fig. 2.7(C)).

The RICH detector will be placed 1.6 m downstream from the target behind the dipole magnet. It will consist of a 1.7 m long gas radiator at 2 mbar overpressure and two arrays of mirrors (Al+MgF<sub>2</sub> coating) and photon detector planes.

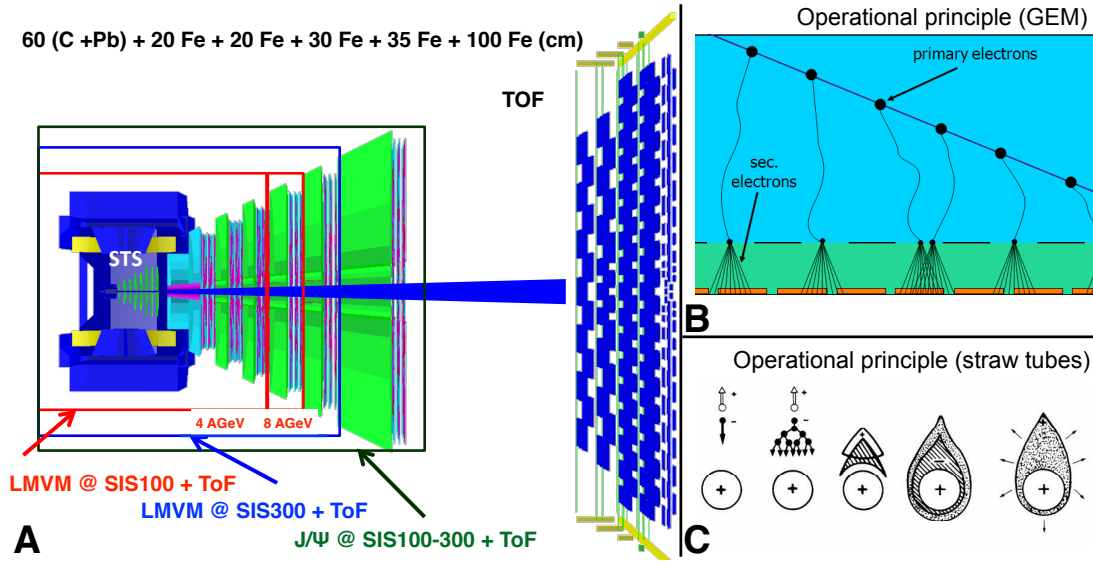

The design of the photon detector plane is based on MAPMTs (Multianode PhotoMultiplier Tubes, e.g. H8500 from Hamamatsu) in order to provide high granularity, high geometrical acceptance, high detection efficiency of photons also in the UV region and a reliable operation.

According to in-beam tests with a prototype RICH of real-size length, one has to expect the order of 100 Cherenkov rings to be seen in a central Au+Au collision at 25 AGeV due to the large material budget in front of the detector. About 22 photons are measured per electron ring. Simulation studies predict that such a high value of photons per ring together with high granularity (approx. 55 000 channels in total) allows the achievement of a pion suppression on the order of 500.

### 2.3.5 Muon Chambers (MuCh)

Since the CBM strategy is to measure both electrons and muons in order to combine the advantages of both probes, the muon detector is also a part of the alternative setup version. The main experimental challenge for muon measurements at CBM is to identify low-momentum muons in an environment of high particle densities.

The MuCh (Muon Chamber) [47] in CBM is placed downstream of the STS,

**Figure 2.8:** (A) The scheme of the MuCh detector configurations, optimized for different physics cases: low-mass vector mesons (shown with red and blue frames) and  $J/\psi$  measurements (shown with a green frame)[47]. The schematic representations of the signal generation process in the GEM detector (B) and the straw tube detector (C).

which determines the particle momentum. The detector will exploit the standard technique of absorber filtering.

The approved complete design of the muon detector system consists of 6 hadron absorber layers and 18 gaseous tracking chambers organised in triplets, placed behind each absorber slab (Fig. 2.8(A)). The first absorber is located inside the magnet and for this reason, is made of 60 cm of nonmagnetic carbon, then iron plates of thickness 20, 20, 20, 30, 35 and 100 cm are installed.

The muon detector system will be built in stages adapted to the beam energies available. The first two starting versions of MuCh (SIS100-A and SIS100-B) will comprise 3 and 4 stations suitable for the measurement of low-mass vector mesons ( $\rho, \omega, \phi$ ) in nucleus-nucleus collisions at 4–6 AGeV and 8–14 AGeV, respectively. The third version of the MuCh system (SIS100-C) will be equipped with an additional iron absorber of 1 m thickness in order to be able to identify muons from charmonium decay at the highest SIS100 energies.

As for tracking planes, different detector technologies will be used depending on the hit density and the rate for a particular detector layer. The first two

stations will consist of the triple Gas Electron Multiplier (GEM) detectors, in order to cope with the 3 MHz/cm<sup>2</sup> hit rate, predicted by simulations. The last one or two stations will be made of the straw tube detectors, due to smaller hit rates and larger areas to be covered. As the last tracking station, behind the thick 1 m absorber, four layers of the Transition Radiation Detector (TRD), which is built for electron identification at CBM, will be used. For the full MuCh version at SIS300, the 5th station will be made of hybrid GEM+Micromegas technology and as the 6th station, after the 1 m iron absorber, again the four TRD layers will be used.

The operational principle of GEM detectors (Fig. 2.8(B)) and straw tubes (Fig. 2.8(C)) are similar and based on the avalanche effect. Straw tubes are drift chambers consisting of a gas filled tube with a conductive inner layer acting as a cathode and an anode wire stretched along the cylinder axis. The detection is based on the electromagnetic interaction between the charged particles traversing the gas inside a straw tube resulting in the gas ionization. Thanks to the applied static electric field in the tube, the electrons of the primary ionization drift towards the anode, while the ions drift towards the cathode. Due to the high electric field strength near the thin anode wire, the drifting electrons gain enough energy to produce an avalanche-like secondary ionization process called gas amplification. Thus, the electric charge collected on the anode is many orders of magnitude higher than that produced in the primary ionization.

### 2.3.6 Transition Radiation Detector (TRD)

The Transition Radiation Detector (TRD) [48] task is to improve identification of electrons and positrons with respect to pions for the momenta larger than 1.5 GeV/ $c$ .

The detection is based on the the effect of transition radiation (TR) emission by an ultrarelativistic charged particle when crossing the boundary between two media with different dielectric constants. The total energy loss of a charged particle during the transition depends on its Lorentz factor  $\gamma = E/mc^2$ .

For the predicted particle momenta, the probability of producing TR by electrons and positrons ( $\gamma > 1.000$ ) is higher than by any other particle, offering the opportunity to separate them from pions. The multiwire proportional chambers

**Figure 2.9:** (A) The scheme of the Transition Radiation detector for SIS100/300 and (B) the geometry of one detector module [48]. In the module schematic signals produced by a pion and an electron are shown. The geometric proportions and the field lines in the drift chamber are accurate [49].

are used to detect produced TR photons.

The current version of the detector consists of 3 stations located at 5 m, 7.2 m and 9.5 m downstream from the target (Fig. 2.9(A)). Each station consists of several detecting layers adding up to a maximum of 10 layers in total.

An individual detector module consists of a radiator and a photon detector. The photon detector is a drift chamber with a 3 cm drift zone and an amplification region of about 6 mm. The drift electrode is glued directly to the radiator.

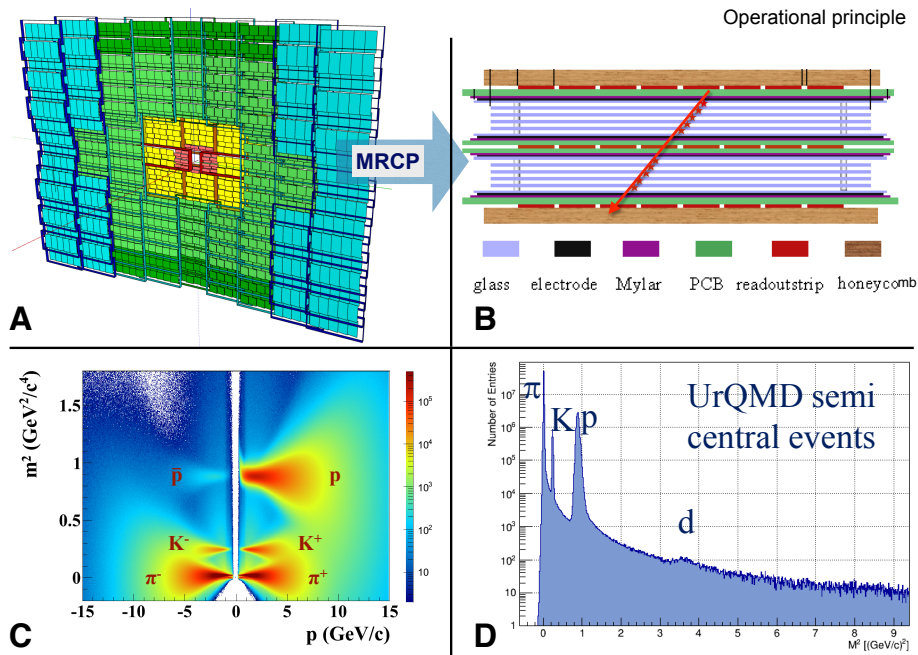

The particles pass through the radiator and the generator of the TR and then enter the conversion and drift region of the readout chamber.

A cross section of a segment of one module of the TRD is shown in Fig. 2.9(B) along with schematic signals from a pion and an electron detected by the drift chamber. The electron-to-pion separation is performed by statistical analysis of

the energy losses in each layer. Additionally, the TRD can serve as a tracking detector, bridging the gap between the STS and the TOF detectors.

The pion suppression factor obtained with 10 TRD layers is estimated around 100 at an electron efficiency of 90%. For measurements at SIS100 one station of TRD with maximum 4 detector layers will be used.

### 2.3.7 Time Of Flight (TOF) detector

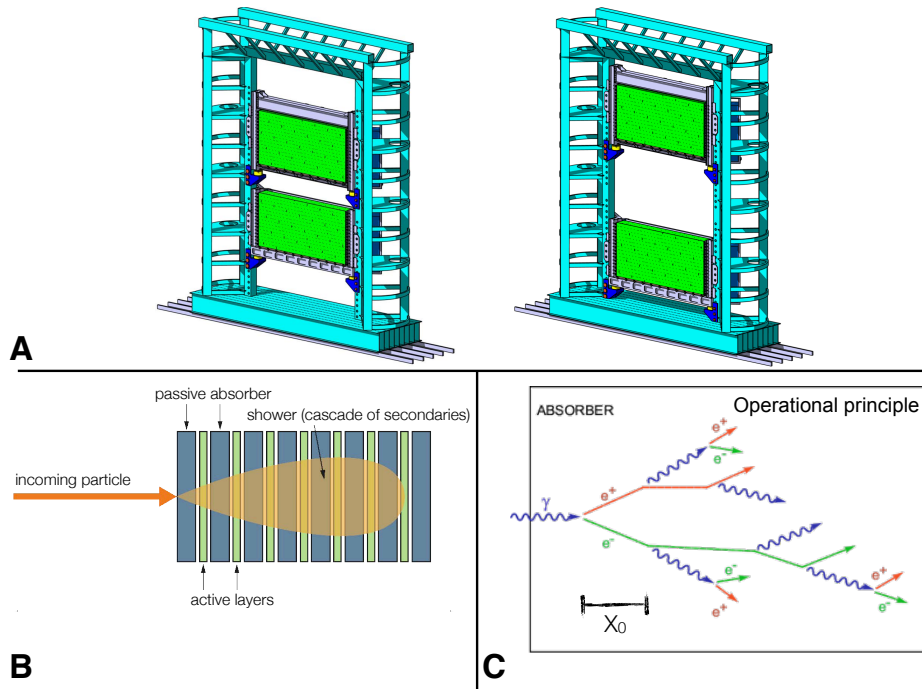

**Figure 2.10:** (A) The scheme of the time-of-flight wall [50]. (B) The structure of the float glass MRPC with 8-strip readout [51]. The simulated 2D squared mass distribution versus momentum and (C) its projection (D).

The time-of-flight measurement will be used for the identification of charged particles: the determination of the particle mass is based on the measurement of the time of flight, the particle momentum and the particle track length.

The TOF detector [50] (Fig. 2.10(A)) is located at a distance of 6 m from the target in the SIS100 configuration version and 10 m in case of SIS300.

The required full system time resolution is on the order of 80 ps.

The simulations predict hit rates of up to 20 kHz/cm<sup>2</sup>. In order to meet these

**Figure 2.11:** (A) The layout of the electromagnetic calorimeter ECAL [53]. (B) A sampling calorimeter scheme and (C) a schematic development of an electromagnetic shower.

requirements MRPC will be used (Fig. 2.10(A)). The MRPC is a stack of resistive glass plates (Fig. 2.10(B)). High voltage is applied to the external surfaces of the stack. The pickup electrodes are attached further out. A charged particle ionizes the gas while traversing. The high electric field amplifies this ionization by an electron avalanche. The resistive plates stop the avalanche development in each gap. However, they are transparent to the fast signal induced on the pickup electrodes by the movement of the electrons. So the total signal is the sum of the signals from all gaps. For the sake of high efficiency there are many gaps. The time jitter of the signal depends on the individual gap width. Thus, in order to achieve good time resolution, the gaps are narrow.

According to simulation studies TOF will provide the separation of kaons from pions for momenta up to  $3.5 \text{ GeV}/c$  and protons from kaons for momenta up to  $6 \text{ GeV}/c$ . The squared mass distributions obtained from the studies are shown in Fig. 2.10(B) and (C).

### 2.3.8 Electromagnetic CALorimeter (ECAL)

A sampling calorimeter, in which the material that produces the particle shower is distinct from the material that measures the deposited energy, will be used to measure direct photons and neutral mesons decaying into photons [52] (Fig. 2.11(A)). The passive absorber and active materials alternate with each other as it is shown in Fig. 2.11(B).

The working principle of calorimeter is based on the total absorption of the energy associated with the incoming particle. The particles cause an electromagnetic shower of electrons, positrons and secondary gammas, and the summed ionization is proportional to and a good measure for the incoming energy (Fig. 2.11(C)).

The ECAL will be composed of modules which consist of 140 layers sandwiched of lead and scintillator sheets. The shashlik modules can be arranged either as a wall or in a tower geometry with variable distance from the target.

### 2.3.9 Projectile Spectator Detector (PSD)

The determination of the reaction plane in nucleus-nucleus collisions is crucial for several measurements, including anisotropic collective flow. The reaction plane is defined by the impact parameter and the beam direction  $z$  (Fig. 2.12(B)). In CBM, the reaction plane can be measured by the forward hadronic calorimeter, referred to as the Projectile Spectator Detector [54] (Fig. 2.12(A)).

The PSD will be used to determine the collision centrality as well as the orientation of the reaction plane. A precise characterisation of the event is of great importance for the analysis of event-by-event observables. The study of collective flow requires a well defined reaction plane which has to be determined by a method not involving particles participating in the collision.

The detector is designed to measure the number of non-interacting nucleons (spectators) from a projectile nucleus in nucleus-nucleus collisions (Fig. 2.12(B)). The PSD is a full compensating modular lead-scintillator calorimeter, which provides very good and uniform energy resolution. It comprises 44 individual mod-

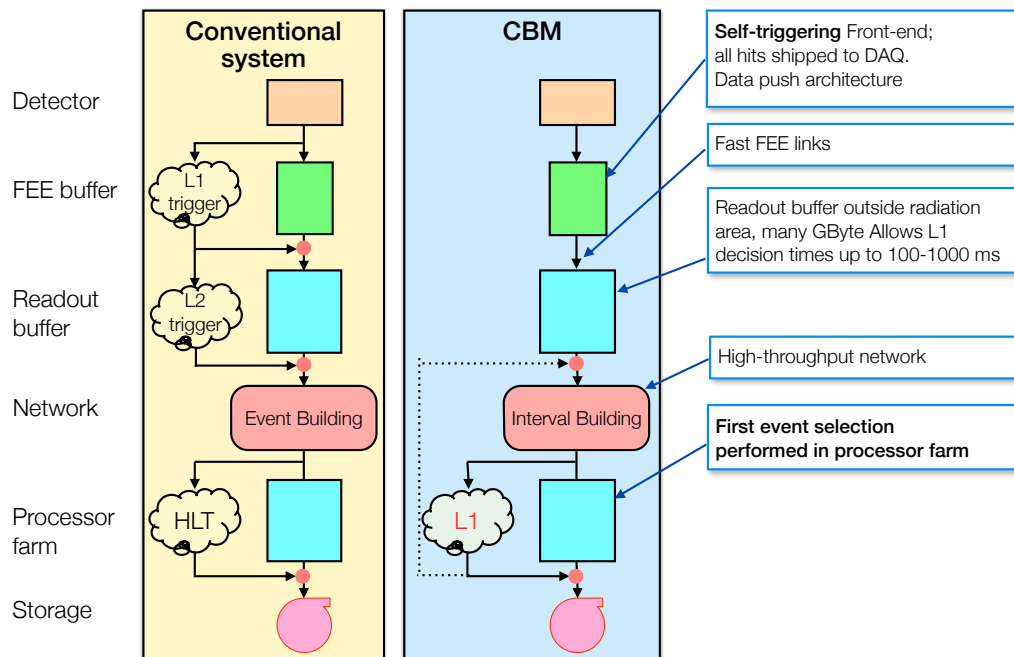

**Figure 2.12:** (A) The layout of the Projectile Spectator Detector (PSD) [54]. (B) The reaction plane by definition contains the impact parameter vector (along the X-axis).

ules, each consisting of 60 lead/scintillator layers.

## 2.4 Data AcQuisition system (DAQ)

Many of the important signals in the CBM physics program are based on rare probe measurements. In order to obtain statistically sufficient data, the detector systems are designed to operate at interaction rates of up to 10 MHz for Au+Au collisions. Together with the high multiplicity of charged particles produced in heavy-ion collision, it leads to huge data rates (up to 1 TB/s), which must be reduced online to an archival rate of about 10 GB/s. The CBM data acquisition and event selection system will perform the task of identifying interesting events and sending them into storage.

The huge collision rates together with the absence of simple trigger criteria resulted in a novel DAQ concept for CBM (Fig. 2.13). The conventional DAQ

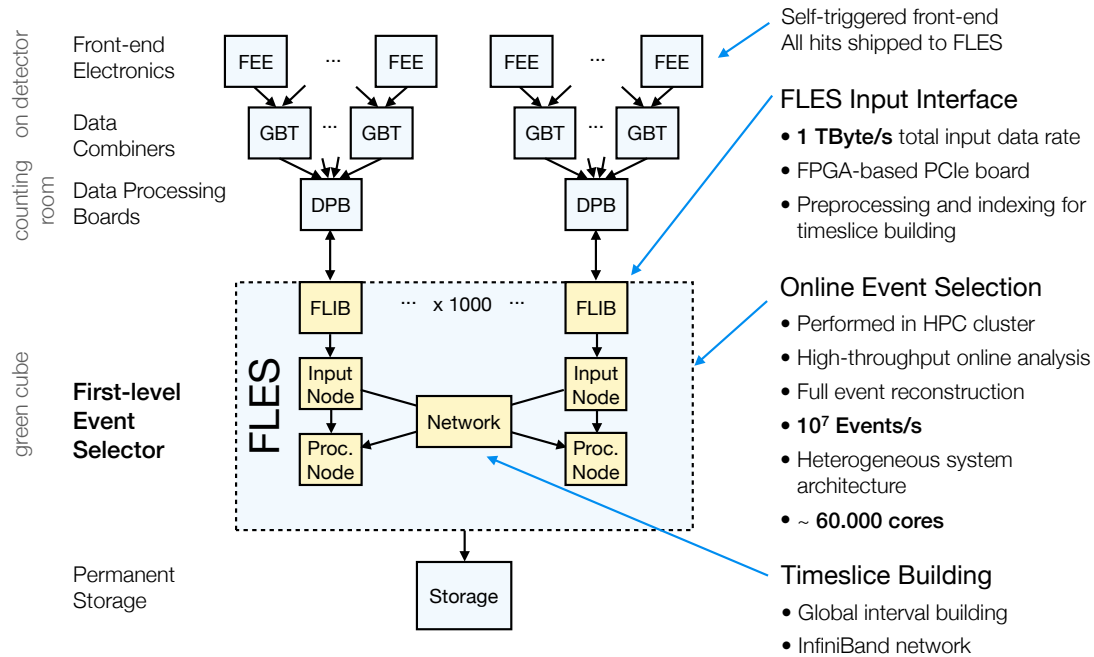

**Figure 2.13:** The CBM data acquisition concept in comparison to conventional systems [55]. Usually, the collected data undergoes several trigger levels, where it gets reduced. This scenario is inapplicable for CBM due to the absence of simple triggers. Instead, the first (L1) trigger will be a High Level Trigger (HLT), running on a computer farm.

system design with triggered front-end electronics permits keeping the event data for a limited time (about a few  $\mu\text{s}$ ) until a quick trigger decision is taken. As soon as a positive decision is chosen, the DAQ sends the selected event either to a higher trigger level or to the archival storage. This DAQ system with a fixed trigger latency is not applicable for the case of CBM in the absence of simple hardware triggers based on the raw data from the detectors.

Unlike the conventional DAQ system in the concept adapted for CBM, all front-end electronics are self-triggered, where each particle hit is autonomously detected and the measured hit parameters are stored with precise timestamps in large buffer pools.

The event building via the association of hits with events is performed later by

**Figure 2.14:** The architecture of the First-level Event Selector (FLES) [56].

processing data from these buffers via a high speed network fabric. The selection and storage of events is performed after (full/partial) event reconstruction in a large computer farm.

Thus, the role of the data acquisition system is to transport data from the front-end to processing resources and finally to archival storage. In this case the system is not limited by decision latency as in a conventional DAQ system, but only by the total computational throughput.

## 2.5 First Level Event Selection (FLES)

The name of the CBM online high-level processing farm, First Level Event Selection (FLES), implies there is no low-level event trigger before this stage. The FLES performs interval/event building on the full input rate of 1 TB/s. After it the online event analysis includes clusterization and feature extraction, tracking in four dimensions (including time) and finally event selection. Assuming an archiving rate of 1 GB/s and an average event size of about 40 kB a maximum

event rate of 25 kHz can be accepted for permanent storage. Thus, if the primary event rate is 10 MHz, the required data reduction factor is at least 400.

The FLES will be a scalable high-performance computer farm. It will consist of different available types of computing devices, including FPGAs at the first stages of the system and heterogeneous many-core CPU/GPU architectures to achieve fast and efficient event reconstruction. The architecture of the First-Level Event Selection farm is summarized in Fig. 2.14. In total, there are 1000 links at 10 GBit/s transmitting data into FLES.

Online event analysis will be performed by processing nodes estimated to require in total approximately 60 000 cores (year 2010 equivalent). A high-throughput network infrastructure will connect all nodes and enable interval building at the full input data rate of 10 MHz.

# Chapter 3

## High Performance Computing

HEP has always been a data-intensive domain due to the fundamental feature of quantum mechanics, namely its probabilistic nature. HEP experiments are aiming to register rare relevant events, which can only be obtained within a large number of observations. In order to achieve this challenging goal, particle physics has done a long way from using bubble chambers with collision rates of about 1 collision per minute to modern HEP detectors with rates counted in MHz.

Thus, modern tracking detectors generate huge amounts of analog data at rates equivalent to petabytes per second, that is beyond the generally known bounds to be considered “Big Data”. It poses a great challenge of collecting, storing and reducing these large volumes of data. The experimental information has to be analyzed online in order to select and store relevant events, since only reducing the data volume by orders of magnitude in real time can allow for meeting the recording rates achievable nowadays. For this reason computing plays a crucial role in HEP.

In fact, HEP experiments are not only one of the main consumers of High Performance Computing (HPC), but also the area, which is pushing the development in computer capability by its constantly increasing computational demands.

This chapter will give a brief overview of existing HPC hardware architectures and software frameworks, which allow for the use of parallel hardware in a convenient and efficient way. Special emphasis will be given to the hardware and software tools, which were used to develop the 4D CA track finder algorithm within the current thesis.

## 3.1 Hardware architecture and its implications for parallel programming

Until 2004 software developers could improve the speed of single-threaded programs without much efforts on their part due to the constant increase in frequency of processors. However, this trend has reached its limits due to the frequency-power wall and physical limitations of semi-conductor technology.

Instead, all computer manufacturers have turned to a parallel architecture as the new HPC paradigm. For the developers it meant that the so-called “free lunch” era [57], when performance was improving with new computer architectures without any contribution from the developers’ side, was replaced by the parallel era, when the performance improvement may only be gained at the cost of programming effort.

Modern computer technologies allow performing a number of calculations simultaneously. In other words computer architectures nowadays are parallel. In order to use such architectures efficiently, one needs to exploit distributed calculations within one super computer — a many- or multi-core server, equipped with vector registers.

Multi-core processors can offer significant performance improvements over their single-core counterparts for certain kinds of parallelized tasks, often demanding new programming paradigms to efficiently utilize the complex architecture involved [58]. Future trends promise that computing power will further evolve in a parallel direction, gaining more cores per processing unit and more elements per vector register.

In this case it is crucial to exploit the full potential of this complex hardware. In order to get maximum performance out of future computer architectures, developers should design programs so that the speed of resulting applications scales with the number of parallel elements in the heterogeneous system. Ideally, implemented algorithms should show linear scalability in a parallel run. Modern parallel architectures present unique challenges for the software designers since the structure of these architectures has significant impact on the way work is scheduled, memory is allocated, and instructions are executed.

Modern applications need to be designed with parallelism in mind from the

very beginning. However, there is no chance to write software, which fully utilize the power of modern complicated computer architectures, without understanding of the hardware, on which the software will be executed.

Thus, achieving this challenging goal is not possible without expertise in understanding underlying hardware architecture. In order to classify all existing parallel systems, they were organized into a coherent and simple taxonomy.

### 3.1.1 Flynn's taxonomy

By far the most commonly used computer architecture classification is the taxonomy [59] proposed by Michael Flynn. The classification characterizes computer designs in terms of the number of instructions streams issued at a time and the number of data elements they operate on. Flynn's taxonomy classifies machines according to whether they have one or more than one stream of each type (Fig. 3.1).

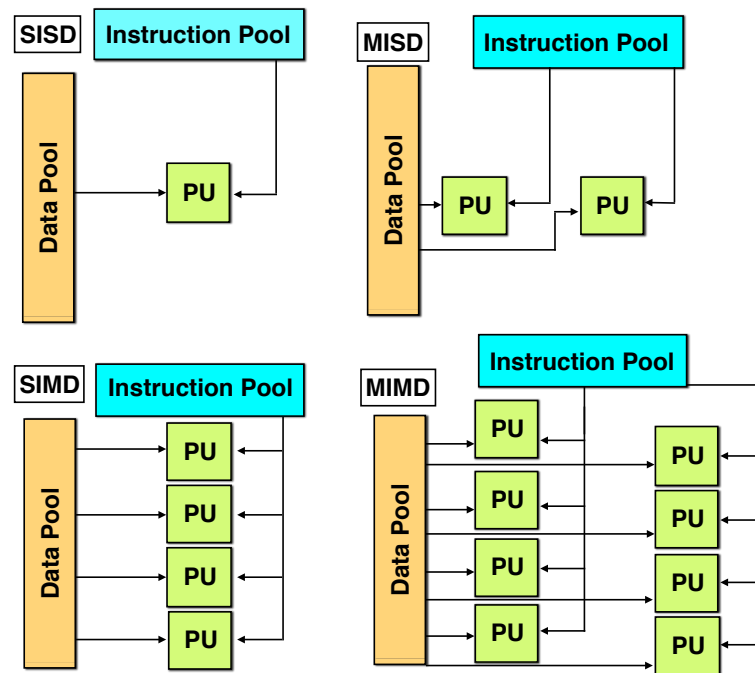

There are four possibilities:

- SISD (Single Instruction stream, Single Data stream),
- SIMD (Single Instruction stream, Multiple Data streams),
- MISD (Multiple Instruction streams, Single Data stream),
- MIMD (Multiple Instruction streams, Multiple Data streams).

The classical von Neumann approach can be described by Single-Instruction-Single-Data (SISD) type. However, SISD is not necessarily completely sequential architecture, since some instructions from the same stream may be executed concurrently (see instruction level parallelism).

The revolutionary alternative was Single-Instruction-Multiple-Data (SIMD), which appeared in the mid-60s and describes performing the same operation over a multiple data set simultaneously. This can be done both in signal-threaded and multi-threaded applications. Multiple-Instruction-Single-Data (MISD) is a rarely used type. Although there were computer architectures to deal with this type of parallelism (such as systolic arrays), there are few applications that can benefit from this type of hardware.

Multiple-instruction-multiple-data (MIMD) programs are by far the most common type of parallel programs, that correspond to multiple processors, each using

**Figure 3.1:** Flynn's taxonomy, which classifies computer architectures by the number of instruction and data streams.

its own data and executing its own program independently.

Different types of computer architectures may exhibit four different types of parallelism. Let us consider each of them in the next section.

### 3.1.2 Parallelism in hardware

Since the processor parallelism is the primary method of performance improvement, it is important to be aware of all available architectural features that brought substantial performance gain. These features can be roughly classified in several categories:

- Instruction-Level Parallelism (ILP, e.g., pipelining, out-of-order superscalar execution, branch prediction),
- Data-Level Parallelism (DLP, e.g., SIMD, vector computation),
- Task-Level Parallelism (TLP, e.g., multi-threading),
- Memory-Level Parallelism (MLP, e.g., hardware prefetcher).

### Instruction-level parallelism

Multiple instructions from the same instruction stream can be executed concurrently, if such feature is provided by the hardware.

If one considers a computer program as a sequence of instructions executed by a processor, an important characteristic of hardware is the number of instructions, that can be issued per clock cycle (IPC). Without the instruction-level parallelism, a processor can only issue less than one instruction per clock cycle ( $IPC < 1$ ). Such computing units were called subscalar processors.

The situation changed in the mid-1980s when the first super-scalar architectures appeared. It was noticed, that instructions can be re-ordered and combined into groups of non-dependent instructions, which are then executed in parallel on corresponding different functional units without changing the result of the program.

**Figure 3.2:** A canonical five-stage pipeline (IF = Instruction Fetch, ID = Instruction Decode, EX = Execute, MEM = Memory access, WB = Register write back) (left side) and a five-stage pipelined superscalar processor, capable of issuing two instructions per cycle (right side). It can have two instructions in each stage of the pipeline, for a total of up to 10 instructions (shown in green) being simultaneously executed.

This hardware feature is called pipelining. All modern processors have multi-stage instruction pipelines. Instructions are broken up into stages (Fig. 3.2, left side). Each stage in the pipeline corresponds to a different action the processor performs on that instruction in that stage. A processor with an  $N$ -stage pipeline can have up to  $N$  different instructions at different stages of completion and thus can issue one instruction per clock cycle. This way pipelining tries to keep every element of the processor busy with some instruction. As a result it increases

instruction throughput.

In addition to that, modern processors also have multiple execution units (Fig. 3.2, right side). Thus, combining multiple execution units with pipelining, processor can issue more than one instruction per clock cycle and achieve superscalar performance ( $IPC > 1$ ).

Pipelining increases instruction throughput by performing multiple operations at the same time, but does not reduce instruction latency, which is the time to complete a single instruction from start to finish, as it still must go through all steps. Indeed, it may increase latency due to additional overhead from breaking the computation into separate steps and worse, the pipeline may stall (or even need to be flushed), further increasing the latency.

### Data-level parallelism

According to Flynn's taxonomy, Data-Level Parallelism (DLP) exploits the SIMD concept. This type of parallelism is more involving, since for efficient execution it requires efforts from the developer's side.

As the name suggests, in case of DLP instructions a single stream of instructions operates concurrently on a set of several data. Usually this term is applied to simple ALU functions, like addition or multiplication. The operations are performed on so-called vector registers filled with a set of elements of the same data type (float, integer etc.) (Fig. 3.3).

**Figure 3.3:** The scheme of SIMD calculations principle: the instruction is executed on a set of different data within the vector register.

Nowadays SIMD instructions can be found to a different extent on most CPU-

like processors, including Intel's SSE, AVX, IMIC, AMD's 3DNow!, IBM's AltiVec, SPE for PowerPC etc. The instructions differ in hardware implementations and register size. For instance, SSE (Streaming SIMD Extensions) works with 128-bit registers, which facilitates simultaneous operation on two 64-bit (8-byte) double precision numbers, four 32-bit (4-byte) floating point numbers, two 64-bit integers, four 32-bit integers, eight 16-bit short integers or sixteen 8-bit bytes. Advanced Vector Extensions (AVX) works with 256 bit registers (8 floats or integers), IMIC — with 512 bit registers (16 floats or integers). In GPUs SIMT (Single Instruction Multiple Thread) approach is used, when a group of cores, each running its own thread, executes the same instruction on a set of multiple data.

The theoretically achievable speed-up factor of SIMD calculations is determined by the number of scalar elements processed within a single instruction, which directly depends on the width of vector register. In addition to that, with longer vectors the SIMD initial load and memory access latency is amortized over a greater number of productive cycles, and thus becomes relatively smaller. This fact explains the long term manufacturing tendency for wider registers.

One more interesting feature of SIMD calculations is that they provide the opportunity to benefit from switching from double precision to single precision by the simple consequence of doubling the number of elements in a vector. This fact brings the issue of algorithm stability in the single precision arithmetic to a new performance-related level.

On the other hand, DLP has certain requirements for the algorithm, for which it can be used efficiently. For instance, conditional execution is mostly not efficient, since it requires expensive data re-arranging or a part of vector width becomes idle. For this reason originally SIMD calculations were tailored to naturally vectorised problems of matrix-oriented computing and media-oriented image processing.

Keeping this in mind, one can conclude that not every algorithm can take the advantage of SIMD calculations. Moreover, after reaching some vector width, only few naturally vectorised algorithms can benefit from further increase of vector length due to the fact that there will not be enough elements to fully fill the vector width.

For this reason, there is a more recent trend of having more registers, each register being quite short compared to the traditional length. This offers more flexibility to the algorithm implementation and allows for more sophisticated compiler optimizations, while reducing hardware complexity.

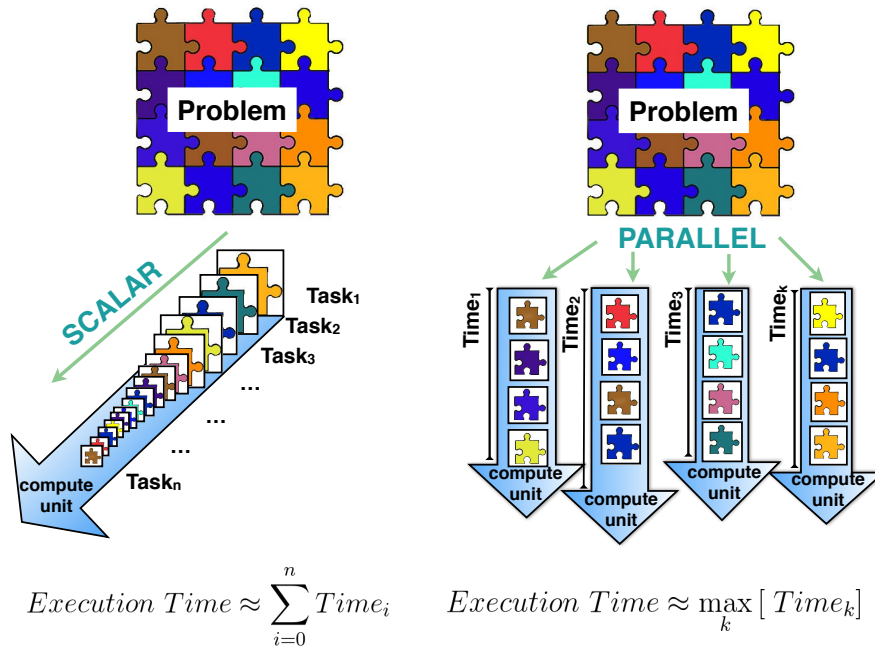

Despite the non-trivial task, some compilers provide auto-vectorization. Unfortunately, in this case the developer usually has no control over the process and in the end gets poor speed-up factor in comparison with potential values.

Summarizing, exploiting SIMD instructions in the algorithm implementations can be a tricky task and strongly depends on the algorithm choice. However effective use of SIMD instructions promises a great speed-up potential, which would be unwise to ignore.

### **Task-level parallelism**

When the evolution of hardware design turned in the direction of parallel architectures, the vendors started to clone the whole core multiple times, allowing multiple threads to perform execution in parallel. As a first step, architects cloned the big cores used in single-core processors multiple times to create multi-core processors. Although these cores were operating with a lower frequency than in an equivalent single-core processor for the lower power consumption sake, still parallel processing provided a much bigger computing power gain than the loss due to core frequency reduction. However full-sized core cloning is limited and in order to gain more parallelism, the vendors have created architectures with simpler cores running at even lower frequencies but numbered in dozens. This massive level of parallelism of many- and multicore architecture can be exploited only by the applications, that have a multi-threaded design.

In contrast to DLP, Thread-Level Parallelism (or TLP) exhibits more flexibility, since in this case generally speaking each thread can perform independent task. This involves executing individual streams of instructions delegated to different cores of a processor simultaneously. Each process maintains its data and instructions, so that it may be considered an independent task, even if processes are performing parts of one global task and synchronized with each other. For this reason this type of parallelism follows the concept of MIMD architecture, if we consider Flynn's taxonomy.

**Figure 3.4:** The scheme of task-level parallelism principle. The tasks are distributed between threads. The execution time is defined by the last thread to finish.

Conceptually, it is straightforward to see why TLP speeds up an execution. If one considers the threads, which are truly independent, then distributing a set of threads among available cores on a processor would reduce the elapsed execution time to the execution time of the last thread to finish, compared to a sequential version which would require the sum of execution times of all of the threads. To achieve the maximum performance the work should be evenly divided among threads in such a way, that they finish execution at the same time. Fig. 3.4 illustrates these conceptual differences between single threading and thread-level parallelism, assuming independence and no thread allocating or scheduling overhead.

Unfortunately, in real life this idealistic scenario is affected by several factors. The main performance impacting factors are: limited level of execution independence and synchronization overhead, scheduling and disproportion in thread load, limited thread memory.

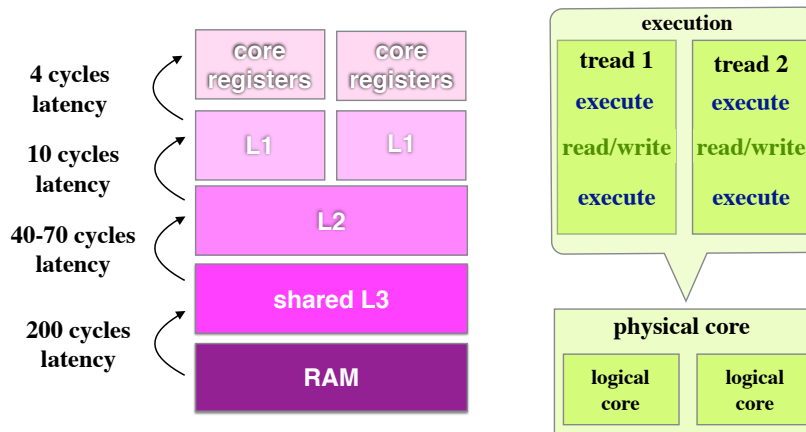

**Figure 3.5:** The tendency of computational and memory access performance: the discrepancy between improvements in the speed of calculations and memory access is growing [60].

### Memory-level parallelism

Following the main parallel architecture trend towards more complexity, modern computers are being equipped with more cores. With the performance improvement it also brings proportional increase of the data demand. This fact poses a challenge to the architecture design with regards to memory bandwidth.

From 1986 to 2000, CPU speed improved at an annual rate of 55% while memory access speed only improved at the rate of 10% (Fig. 3.5). This problem of growing discrepancy between improvements in the speed of calculations and memory access is known as Memory Wall. Thus, the latency and limited communication bandwidth are the main barriers to computer performance improvements nowadays.

This bottleneck is usually removed or at least attenuated by caching, or in other words attaching a layered structure of fast, but small memory directly to each core (Fig. 3.6, left side). Terms “fast” and “small” here mean that main memory access can be two orders of magnitude slower than first-level cache, while the main memory is three to five orders of magnitude larger [61]. This cache is intended to store copies of the data from frequently used main memory locations. In case of CPU these data copies are coherent, which means that at any moment the copies stored in any layer of cache are guaranteed to coincide with values in the

**Figure 3.6:** The average memory access latency in cycle counts for different layers of cache in CPU (left side). The scheme of hyper-threading technology principle (right side): while one thread is fetching the data, the other can execute an instruction due to the duplicated register sets inside one physical core.

main memory. If the cache is used properly, it can greatly reduce the time that the CPU waits for data to be fetched from the Random-Access Memory (RAM).

If cache is not used in an optimal way, cache misses will occur often. A cache miss refers to a failed attempt to access a piece of data in the cache, which results in a main memory access with much longer latency. If single cache misses generated by a single thread can be grouped and executed in a combined manner, overall performance is improved. The term memory-level parallelism (MLP) refers to the number of single cache misses that can be generated and executed in a combined way. Many microarchitectural techniques have been developed to increase MLP (e.g. prefetchers, which can bring data from the next level memory hierarchy to the closer cache in advance). Current architectures have ever growing caches to improve the average memory reference time to fetch or write instructions or data.

Although there will be bigger caches and higher memory bandwidth in the future, they must be managed and used in the most efficient manner. First, when the size of the total data set is larger than the size of cache, we must re-use the data in the cache as many times as possible before the data is put back to the main memory to avoid cache misses. Second, in the application, we should

minimize the number of random memory accesses and try to keep the data locally in order to benefit from the lined manner of cache reading. There was no efficient random-access machine model for parallel computing established.

On the other hand, in case of many-core processors, if multiple threads attempt to write to the same memory location at the same time, they must wait to resolve conflicts. Thus, having threads writing to different areas of shared memory would be preferable in decreasing the likelihood of incurring these time-consuming conflicts.

By far the most popular solution to this problem is Non-Uniform Memory Access (NUMA) architecture. The idea is to place data used by one particular core physically closer to that core in the memory. The opposite situation we could observe in so-called UMA (Uniform Memory Access) architecture, where each processor must use the same shared bus (or another type of interconnect) to access shared memory, resulting in a memory access time that is uniform to all processors.

In the NUMA shared memory architecture, each processor has its own local memory module, which it can access directly with a distinctive performance advantage. At the same time, it can also access any memory module belonging to another processor using a shared bus.

Like most other processor architectural features, ignorance of NUMA can result in subpar application memory performance. In order to benefit from the NUMA architecture features, it is important that one keeps the data used by a certain processor in the corresponding memory slot.

## **3.2 Architectures specification**

This section will briefly illustrate modern computer architecture features on the examples of several recent microprocessors and computer systems.

### **3.2.1 CPU architecture**

To illustrate the complexity of modern CPUs, let us consider lxir039 server at GSI (Fig. 3.7). Typically modern CPUs have 2 to 4 sockets. The lxir039 server

contains 2 Intel Xeon X5550 CPUs, connected with each other via Quick Path Interconnect (QPI) [62].

The Intel Xeon CPU X5550 is a server processor that was first available for purchase in March 2009. It operates at a stock clock speed of 2.67 GHz. It has a 4-core model, resulting in a high multi-tasking potential. In addition to that, this processor supports Intel Hyper-Threading Technology (HTT) [63].

The HTT results in the fact that for each of 4 cores, that are physically present, the operating system addresses two virtual or logical cores, and shares the workload between them when possible. For this reason the number of independent instructions in the pipeline gets increased and the advantage of superscalar architecture can be used in a more efficient way.

It becomes possible since architecturally a core with HTT consists of two logical cores, each of which has its own processor architectural state. HTT works by duplicating certain sections of the processor, those that store the architectural state, but not duplicating the main execution resources.

Each logical core has its own Advanced Programmable Interrupt Controller (APIC), and, thus, can be individually halted, interrupted or directed to execute a specified thread, independently from the other logical processor sharing the same physical core. Also, each logical core has its own full set of registers.

However, unlike the case of two independent physical cores, the logical core in a hyper-threaded processor share some execution resources: execution engine, including Arithmetic Logic Unit (ALU), Floating Point Unit (FPU), and Vector Processing Unit (VPU), caches, and system bus interface.

The main HTT principle is illustrated in Fig. 3.6 (right side): when one logic core stalls due to a cache miss or data dependency and is waiting for data, the other one can use those execution resources to execute another scheduled task. The extent to which execution can benefit from the presence of HTT depends on the needs of a certain application and was estimated by Intel to performance gains of up to 30% [64].

For example, the lxir039 server at GSI (Fig. 3.7) is equipped with two Intel Xeon X5550 processors and can operate in total with 16 threads in parallel. Following the NUMA concept 24 GB of RAM is attached to each CPU. QPI allows CPUs to access remote memory of each other.

**Figure 3.7:** The structure of the lxir039 server at GSI, which is equipped with two Intel Xeon X5550 processors. Due to HTT, it can operate in total with 16 threads in parallel. Each core of CPU has 32 KB of L1 cache and 256 KB of L2 cache. 8 MB of L3 cache memory is shared among the cores of a CPU.

As for the cache memory, each core of the Intel Xeon X5550 CPU has 32 KB of L1 cache for instructions, 32 KB of L1 cache for data and 256 KB of L2 cache for data and instructions. In addition, each CPU contains 8 MB of L3 cache memory, which is shared among the cores of a CPU.

If one keeps in mind, that vector registers contain up to 4 float or integer data elements due to SSE instructions, the total pure hardware potential speed-up factor of the lxir039 server with respect to the one-core scalar operation can be calculated as follows:

$$f = 2 \text{ sockets} \cdot 4 \text{ cores} \cdot 1.3 \text{ threads} \cdot 4 \text{ SIMD} \approx 42.$$

### 3.2.2 GPU architecture

When the increase of CPU clock speed started to stagnate and the computer architecture vendors started to explore parallel hardware, a new initially non-general-purpose and highly parallel processor design started to be used in Graphics Processing Unit (GPU). GPUs were initially used for rendering graphics only. However, this has changed in the course of time.

**Figure 3.8:** The structure of streaming multiprocessor of the Nvidia GTX 980 GPU [65, 66].

A GPU architecture has several major features, which differ from the CPUs. First of all, while GPUs can have hundreds or even thousands of cores, these cores have smaller frequency than a CPU core and are missing some features.

The missing features include interrupts and virtual memory, which are required to implement a modern operating system. It has a major consequence on the way an application for a GPU can be designed. Secondly, the speed of access between a CPU and its larger pool of RAM is slower than GPUs, which typically contain a smaller amount of more expensive memory that is very much faster to access.

In other words, CPUs and GPUs have significantly different architectures that make them better suited to different tasks. A GPU can handle large amounts of data in many streams, performing relatively simple operations on them, but is not suited to heavy or complex processing on a single or a few streams of data. A CPU is much faster on a per-core basis and can perform complex operations on a single or few streams of data more easily, but is not as efficient in handling as many streams as GPU simultaneously.

While GPU has many benefits such as more computing power, larger memory bandwidth and low power consumption with regard to high computing ability, there are some constraints as far as full utilization of its processing power is concerned. These constraints make performance optimization more difficult.

On top of this, the debugging environment is not as powerful as in general CPU. Therefore, developing a code with GPU can take more time and needs more sophisticated work and fine-tuning. Being heavily parallel, the GPU architecture requires a developer to cope with massive data partitioning and synchronization. Often, the algorithms should be heavily redesigned in order to achieve the maximum possible performance running on GPU, so that a new parallel algorithm for GPU has to be developed.

Let us consider the architecture specification of one of the most recent NVidia GPUs — NVidia GTX 980 [65]. Following the trend towards higher core count, this card has 2048 cuda-cores, which have a fully pipelined integer arithmetic logic unit (ALU) and floating point unit (FPU).

The cores are grouped into streaming multiprocessors of 128 cores. The structure of the streaming multiprocessor is illustrated in Fig. 3.8. The L1 data and instruction cache is shared by all cores within the streaming multiprocessor, while L2 cache is available to all streaming multiprocessors. The card has 4 GB main memory with 224.3 GB/s memory bandwidth.

### 3.2.3 Intel Xeon Phi architecture

Starting in 2007, Intel was working on developing its own powerful GPU, which they code-named Larrabee. Unlike many GPUs, Larrabee would not consist of many special-purpose computing units but of numerous modified Pentium processors that ran x86 code instead. Armed with experience gained from the Tera-scale program, Intel was aiming at developing an accelerator card that could compete with NVidia's Tesla GPUs. After initial prototypes underwent tests in research institutions, this resulted in an accelerator card, code-named Knights Corner, which was commercially available as the Intel Xeon Phi since early 2013.

The Xeon Phi was aimed to combine the advantages of CPU and GPU architectures: while being highly parallel processing design it allows using standard CPU programming tools, thanks to its PC-related architecture. For this reason the Xeon Phi is capable of running existing software with significantly fewer modifications. It supports CPU programming tools such as MPI, OpenMP and Intel TBB, etc. Thus, the Xeon Phi has the flexibility of a coprocessor that can also host an operating system.

The Xeon Phi is available as a PCI Express (Peripheral Component Interconnect Express) card in configurations that differ with respect to the number of available cores (57, 60, or 61), memory size (6, 8, or 16 GB), clock speed (1053, 1100, or 1238 MHz), and cooling concept (active or passive).

The basic architecture is the same for all cards: the Xeon Phi's CPU cores are based on 22 nm manufacturing technology. In this architecture, a single in-order core is replicated up to 61 times in Intel Xeon Phi [67] design and placed in a high performance bidirectional ring network with fully coherent L2 caches (Fig. 3.9). Each of the cores supports four hyper-threads to keep the core's computing process busy by pulling in data to hide latency, resulting in up to 244 threads in total.

The data cache allows simultaneous reading and writing. Thus, cache line replacement can be done within a single cycle. The L1 cache consists of 8 ways set associative 32 KB L1 instruction and 32 KB L1 data cache. The L1 cache access time is approximately 3 cycles. L2 cache is 8 way set associative and 512 KB in size shared among four threads and there is a hardware prefetcher to

**Figure 3.9:** The structure of the Intel Xeon Phi [68].

prefetch cache data. The L2 caches between the cores are fully coherent. Unlike most multiple-core processors, the Xeon Phi provides no shared cache between the cores. The cache is unified, so that it caches both data and instructions. Up to eight GDDR-5 memory controllers use two channels to connect the memory (up to 16 GB) to the ring bus, to which the PCIe interface is also connected.

The Intel Xeon Phi cores have dual issue pipelines with Intel 64 instruction support and 16 floating-point (32-bit) wide SIMD units with FMA support that can work on 16 single precision or 8 double precision data. The instructions can be pipelined at a throughput rate of one vector instructions per cycle. Vector units of cores consist of  $32 \times 512$ -bit vector registers and 8 mask registers to allow predicated execution on the vector elements.

The Intel Xeon Phi is a strong competitor on the HPC market, since it offers about three times the raw performance in floating-point operations per second (1.2 TFLOPS) for a slightly higher price than, for instance, NVidia Tesla cards [69]. The next generation of Intel Xeon Phi Knights Landing is about to appear with 14 nm manufacturing technology, higher number of cores and memory bandwidth.

### 3.3 Software tools for parallel programming

After frequency scaling performance gain was over and CPU manufacturers started offering CPUs with more computational cores instead of faster CPUs, this fact had two major consequences on the developers approach towards applications. First of all, the performance improvement of application nowadays mostly depends on the developer, who optimizes the application in order to get the maximum speedup with a certain parallel architecture. Secondly, the extent to which a certain application can benefit from using parallel architecture depends on the problem at hand and the choice of algorithm.

Thus, the limiting factor for the performance nowadays is the ability to write applications in a way that they scale with the core counts of the parallel architecture. This also means outlining the applications for the concurrency from the very beginning, so that they can gain speedup from future architectures with higher core counts without rewriting the code again.

Let us consider several software tools and frameworks, which allow designing both SIMD-ized and multithreaded parallel applications.

Parallel programming is, first and foremost, a parallel formulation of an algorithm, and only then its implementation in a parallel language. The hardware provides us two levels of parallelization: a task level parallelism working with cores and threads, and a data level parallelism working with SIMD vectors.

If the algorithm allows organization of parallel streams of data, which are processed in the same way, like fit of several tracks, these parts can be SIMDized and run without using extra hardware, but rather on vectors within the same threads. For that one can use the auto-vectorization, which is provided by the compilers. Unfortunately, this brings typically (and unpredictably) about 20% speedup, which is almost negligible compared to the potential factor 4/8/16. In order to reach the maximum (depending on the data level parallelism of the algorithm), one can program using the SIMD extensions directly or using the SIMD header files or the more advanced Vc library.

In order to reveal the performance potential of parallel architecture, the algorithm and its implementation should be developed under certain conditions. In order to benefit from vectorization, the algorithm must allow organization of

parallel streams of data, which need to be processed in the same way. In this case organization of the data structure becomes particularly important, since the SIMD vector has to be filled with meaningful data during all stages of algorithm execution with minimal fraction of the time-costly data snaffle.

### 3.3.1 Header files with overloaded instructions

After vectorized calculation appeared, the complexity of designing and understanding efficient algorithms has increased dramatically. This challenging task can be simplified by implementing supporting methods and concepts. One option would be to exchange direct employment of complex intrinsics by the use of supportive header files [70]. The main idea is to overload arithmetic, binary, logical and comparison operators for the vector types with simple and convenient operators used for scalar calculations.

The header files overload the SIMD instructions implementing the operands and inlining the basic arithmetic and logic functions [73], that turn complex and puzzling code into intuitive, compact and readable syntax. For instance, a simple code for calculation of a polynomial function of the first order, which is written using SSE instructions, is:

```
_m128 y = _mm_add_ps(_mm_mul_ps(a,x),b);
```

The same function, but implemented using the header file, recovers the scalar-like form:

```
fvec y = a*x + b;
```

with overloading

```
friend fvec operator+( const fvec &a,
const fvec &b ) {
return _mm_add_ps(a,b); }
friend fvec operator*( const fvec &a,
const fvec &b ) {
return _mm_mul_ps(a,b); }
```

in the header file.

As one can see, the code, implemented with support of the header files, pretty much coincides with a scalar-like version. The CPU-specific SIMD extensions, hidden in the header files, can be chosen depending on the CPU type, as well as the true scalar header implementation for debugging and testing.

### 3.3.2 Vector Classes (Vc)

One more but more profound and extended option of simplifying the usage of SIMD instructions is the Vc library [71, 72]. The library was designed to support developers in the creation of portable vectorized code with existing implementations for SSE, LRBni or a scalar fallback. Its capabilities and performance have been thoroughly tested. It provides portability of the source code, allowing full utilization of the hardware SIMD capabilities, without introducing any overhead.

It has an intuitive interface and provides portability between different compilers and compiler versions as well as portability between different vector instruction sets. Thus an application written with Vc can be compiled for AVX, SSE, IMIC and others SIMD instructions.

For instance, the code for calculation of a polynomial function of the first order, which is written using the Vc library looks like:

```
float_v y = a*x + b;
```

In a fashion similar to the header files it overloads arithmetic, binary, logical and comparison operators and functions for the vector types. However, in addition to that it contains functionality for so-called horizontal operations. In contrast to common vertical operation (e.g. sum of two vector variables), horizontal operations require the operation to be done within the elements of a single vector, for instance, sorting the elements of a vector.

Another important functionality included into the Vc library is an option of vectorised implementation of conditional code. Usually condition branchings in the algorithm are implemented using an “if” operator. It poses a challenge for vectorised execution, since requires an option of conditional assignment/write-masking. Since it was not supported in the original C/C++ syntax, a new syntax has been offered by the Vc library. For example, an absolute value of a vector type variable can be calculated as:

```
float_m mask = ( a < 0 );  
a(mask) = -a;
```

All negative entries of variable  $a$  will be replaced by positive values.

Additionally Vc provides the special functionality to ease the access to arrays of scalars with vector types. It automatically aligns and pads the memory to allow fast vector in the full index range. The random memory access functionality is provided by the gather and scatter functions. For example: gather fills a vector  $a$  from an array  $A$  taking elements with indexes stored in a vector  $I$ :

```
a.gather( A, I );
```

scatter does the opposite — it fills array entries from a vector:

```
a.scatter( A, I );
```

Here it is worth mentioning that Vc library with all its rich functionality is a comprehensive package, which requires a proper installation procedure. For this reason in some simpler cases, one does not necessarily need to install Vc library but can use a simpler headers files approach.

### 3.3.3 Open Multi-Processing (OMP)

At task level parallelism one localizes independent parts of the algorithms and run them in parallel on different cores or threads with or without synchronization between the processes. It can be implemented using, for instance, the ITBB or OpenMP [74] frameworks.

The OpenMP is an API (Application Programming Interface), which supports multi-platform shared-memory parallel programming. It defines a simple interface to create a multithreaded application. The API consists of compiler directives, library routines and environment variables.

OpenMP provides the developer with a certain flexibility, since it exploits the fork-join parallelism programming model. Due to this programming model the developer can decide which part of the program should be run in parallel and which part, if needed, should stay with sequential run. In the beginning of execution the master thread is created. At the point when the calculation should

**Figure 3.10:** An illustration of the OpenMP multithreading join-fork model, where the master thread forks off a number of threads which execute blocks of code in parallel.

be parallelised additional threads are created and the task is distributed between them (Fig. 3.10). The model also allows nested parallelism. It means that a parallel region is created inside an already existing parallel region.

The interface allows the developer to make relatively minor changes in the code in order to switch to the multithreaded version. The user prompts OpenMP, which section of the code should be run in parallel, marking the section with a preprocessor directive:

```
#pragma omp parallel
```

There is a special directive, which tells the compiler to auto-parallelize the for loop with OpenMP:

```
#pragma omp parallel for
```

Since OpenMP is designed for shared-memory parallel programming, threads can communicate with each other via common variables. By default all variables, which are available to a certain thread, are shared and can be modified. If a certain variable is declared private, a local copy of this variable will be created for each thread. The copies are not coherent.

On top of that OpenMP offers a variety of synchronization tools in order to avoid race conditions and obtain correct results. That includes high level directives like `omp critical`, `omp atomic` and `omp barrier`, as well as a set of low level functionality like `lock`.

OpenMP also contains a set of runtime library routines, which allow, for instance, setting and checking the number of threads, checking the maximum number of threads, getting the number of a current thread, checking the number of cores in a computer, to control the nested parallelism, operating with the simple lock functionality etc. They can be available by including the file:

```
#include <omp.h>
```

As for enabling the OpenMP directives, the only action required from the user is adding an appropriate flag during the compilation.

### 3.3.4 POSIX library

Although computer vendors have implemented threads in their operating systems for decades, there was no standardization until 1995, when a standard for thread programming was established as part of the Portable Operating System Interface (POSIX) standard [75, 76]. In particular, POSIX 1003.1c is the portion of the overall POSIX standard covering threads. It includes the functions and APIs that support multiple flows of control within a process. Threads created and manipulated via this standard are generally referred to as Pthreads. Prior to the establishment of Pthreads, thread APIs were hardware-vendor-specific, which made portability of thread-parallel applications an oxymoron.

The libraries using this standard are also called Pthreads. To use this library, the corresponding header file should be included:

```
#include <pthread.h>
```

Pthreads defines a set of C programming language types, functions and constants. Pthreads allows creating and manipulating threads manually. For example, it allows setting a permanent thread to core affinity, which can be particularly useful in the case of NUMA architecture.

By default the threads are allocated to processors by the runtime environment, which takes into account different factors, such as processor usage or machine load. It can happen, that the thread can migrate to another CPU. For the NUMA architectures it is preferable to use only local RAM for maximum performance. And if the thread would be moved to another CPU, all data used by this thread

would be located in the remote RAM. In order to prevent such migrations, which can ruin the performance, each thread can be pinned to a certain core.

# Chapter 4

## Reconstruction of particles trajectories

The advances in accelerator physics, improved detector technologies together with increased computing power have enabled the HEP experiments collision rates and energies, which were never available before. As a direct consequence, the task of processing the experimental data is getting more and more complicated.

The increased collision energy has led to a more complicated event pattern with a higher trajectory multiplicity. The modern event rates, in turn, are limiting the time available to reconstruct the above mentioned complex collision patterns. The collision patterns are reconstructed via reconstruction of trajectories (tracks) of charged particles, which leave hit measurements as they cross detector planes.

The event reconstruction consists of four stages:

- track finding,
- track fitting,
- particle identification,
- search for short-lived particles.

Although stages of track finding and track fitting are strongly related, traditionally they have been seen as two separate tasks. Specifically, the task of track finding (Fig. 4.1) is a pattern recognition problem of combining into groups hit measurements from the detector data, produced by the same particle, in order to reconstruct the trajectory of the particle. After the measured hits are grouped

**Figure 4.1:** Traditional steps of track reconstruction: track finding and track fitting. Track finding groups hit measurements into reconstructed tracks. Track fitting fits reconstructed tracks in order to obtain track parameters afterwards.

into reconstructed tracks, each track can be individually fitted in order to estimate track parameters out of the measured hits in the presence of noise. This procedure is called track fitting (Fig. 4.1).

Track finding usually takes as an input raw detector hit measurements at the very first event reconstruction phase, when no data reduction can be done yet. Therefore this stage of event reconstruction is often considered the most challenging and time-consuming part of the whole reconstruction procedure.

However, the tendency is that the borders between the track finding and track fitting tasks are getting more and more subtle. The connection between the tasks is becoming stronger. Thus, nowadays the track finding often includes the estimation of parameters in a way that can help improving the search for the next measurement for the reconstructed track with refined fitted parameters. The tendency is mainly driven by the Kalman filter track fitting algorithm and its recursive nature. Let us consider this method in detail in the next section.

## 4.1 Kalman-filter-based track fit

### 4.1.1 The conventional Kalman filter method

As a result of track finding the detector measurements are grouped into sets of hits which, ideally, were produced by a specific particle. The task of track fitting is to estimate track parameters and their errors in order to get kinematical properties of particles, which will later allow for reconstruction of short-lived particles, and, finally, for the physics analysis.

Usually track fitting algorithm exploits the so-called track model, which is a theoretical assumption on the equation of motion for charged particles in the volume of a tracking detector. Several effects have an influence on the particle motion, which the track model cannot take into account in a simple way, namely multiple scattering, ionization and radiative energy loss. These effects add perturbations and affect the reconstruction of the particle kinematical properties. Their influence on the obtained fitted parameters can be correctly taken into account with a proper track fitting method. The most common algorithm in HEP nowadays, used for track fitting, is the Kalman filter method [77, 78, 79, 80].

In principle the track parameters can be derived from the hit measurements by applying the least squares fit. However, in real life cases it is preferable to use the Kalman filter method, since its recursive nature allows for a computationally simpler and numerically optimized implementation. Namely, the method in its calculations needs to operate with matrices, whose dimension equals to the number of fitted parameters, while the least squares fit operates with a matrix with the dimensionality of the number of measurements in the track.

The Kalman filter method has found a wide range of applications thanks to its features, namely:

- an optimal estimate (unbiased with minimal dispersion) as a result of the fitting procedure,
- its recursive nature, which allows to perform the fitting of a partially reconstructed track during track finding,
- does not need a global track model valid for the entire track length, but a local track model valid only between consecutive measurements.

Let us consider a dynamic system, whose evolution in time is fully described with a state vector  $\mathbf{r}^t$ , consisting of several system parameters. The fitting procedure is supposed to provide as a result an estimate of the state vector  $\mathbf{r}^t$  based on a set of measurements. The Kalman filter method obtains an optimal estimate  $\mathbf{r}$  of the state vector  $\mathbf{r}^t$  based on the measurements of this state vector  $\mathbf{m}_k$ ,  $k = 1 \dots n$ , which may be contaminated with noise. The method starts with an initial approximation  $\mathbf{r} = \mathbf{r}^0$  and improves this estimate in a recursive way, consistently taking into account each measurement, providing as a result the optimal estimate after adding the last measurement.

The estimated state vector  $\mathbf{r}^t$  can change from one measurement to the other. For example, usually measurements are taken at different time and space points. Therefore before adding the information of  $k$ -th measurement to the estimate, the evaluation of the system by this time has to be taken into account. So that the estimate and state vector correspond to the same moment. The estimate  $\mathbf{r}$  has always some finite precision — the error  $\boldsymbol{\xi}$ , defined as the difference between the estimate and the actual value of the estimated state vector. In order to keep the track of the error  $\boldsymbol{\xi}$ , let us introduce a covariance matrix as follows:

$$\mathbf{r} = \mathbf{r}^t + \boldsymbol{\xi}, \quad (4.1a)$$

$$C = \langle \boldsymbol{\xi} \cdot \boldsymbol{\xi}^T \rangle. \quad (4.1b)$$

The method assumes a linear model of measurements, which means that the state vector should linearly depend on the measured parameters. Thus:

$$\mathbf{m}_k = H_k \mathbf{r}_k^t + \boldsymbol{\eta}_k, \quad (4.2)$$

where  $H_k$  is called measurement model and  $\boldsymbol{\eta}_k$  is an error of the  $k$ -th measurement.

The Kalman filter method assumes that the error of the measurement and the process noise are unbiased and uncorrelated not only mutually, but also in time (white noise) and their covariance matrices  $V_k$  and  $Q_k$  are known:

$$\begin{aligned} \langle \boldsymbol{\eta}_k \rangle &= \langle \boldsymbol{\xi}_k \rangle = \mathbf{0}, \\ \langle \boldsymbol{\eta}_k \cdot \boldsymbol{\eta}_k^T \rangle &= V_k, \\ \langle \boldsymbol{\xi}_k \cdot \boldsymbol{\xi}_k^T \rangle &= Q_k. \end{aligned}$$

The conventional Kalman filter method is derived for a linear dynamical system, which means that the evolution of the system between two consecutive measurements  $\mathbf{m}_{k-1}$  and  $\mathbf{m}_k$  is described by a linear equation:

$$\mathbf{r}_k^t = F_{k-1} \mathbf{r}_{k-1}^t + \boldsymbol{\nu}_k, \quad (4.3)$$

where  $F_{k-1}$  is a linear propagation operator, which relates the state at step  $(k-1)$  to the state at step  $k$ ,  $\boldsymbol{\nu}_k$  is a random process noise between the measurements  $\mathbf{m}_{k-1}$  and  $\mathbf{m}_k$ , which cannot be taken into account in the prediction matrix  $F_{k-1}$ .

The algorithm works in steps: starting with an initial approximation of the state vector and the covariance matrix (initialization stage) it estimates the system state at the point of the measurement (propagation stage) and corrects this estimate and updates the covariance matrix, taking into account the measurement with a certain weight (filtration stage). The algorithm performs in a loop the propagation and the filtration stages until the last measurement is added. Thus, the equations of Kalman filter fall into 3 groups: initialization, prediction and filtration, as it is shown in Fig. 4.2. Let us consider specific equations for each of the stages.

**Initialization:** The algorithm starts with initializing the state vector with some initial prediction  $\mathbf{r}_0$ , if one is available, or alternatively with arbitrary values. In this case the covariance matrix reflects low confidence level of the initial estimate  $\mathbf{r}_0$ :  $C_0 = I \cdot \text{inf}^2$ , where  $\text{inf}$  stands for a large number.

**Prediction/Propagation:** If the state vector is expected to change between two measurements, the estimate and its covariance matrix needs to be changed accordingly. The current estimate of the state vector and the covariance matrix at the measurement  $\mathbf{m}_{k-1}$  are propagated to the point of the next measurement, while taking into account the process noise:

$$\mathbf{r}_k^- = F_{k-1} \mathbf{r}_{k-1}^+, \quad (4.4a)$$

$$C_k^- = F_{k-1} C_{k-1}^+ F_{k-1}^T + Q_k, \quad (4.4b)$$

where  $\mathbf{r}_{k-1}^+$ ,  $C_{k-1}^+$  — the estimate and the error covariance matrix, obtained at the previous measurement,  $\mathbf{r}_k^-$ ,  $C_k^-$  — predicted estimate of the state vector after the influence of the process noise  $Q_k$ . For the first time the initialization values are propagated, since there are no measurements yet at this point.

**Figure 4.2:** The block diagram scheme of the conventional Kalman filter [77].

**Filtration/Update:** The predicted state vector and the covariance matrix are updated with the information the new measurement brings, in order to get their optimal estimate at this stage. First, correction term — the residual, which is the difference between the estimate and the actual measurement, is calculated:

$$\boldsymbol{\zeta}_k = \mathbf{m}_k - H_k \mathbf{r}_k^- . \quad (4.5)$$

The next element of the filtration step is the weight matrix  $W_k$ , which is calculated as the inverse covariance matrix of the residual:

$$W_k = (V_k + H_k C_k^- H_k^T)^{-1} . \quad (4.6)$$

The weight matrix  $W_k$  defines the influence of the  $k$ -th measurement in the total  $\chi^2$ -deviation of the obtained estimate  $\mathbf{r}_k^+$  from the measurements  $\mathbf{m}_1, \dots, \mathbf{m}_k$ :

$$\chi_k^2 = \chi_{k-1}^2 + \boldsymbol{\zeta}_k^T \cdot W_k \cdot \boldsymbol{\zeta}_k . \quad (4.7)$$

The state vector estimate is corrected by a weighted residual:

$$\mathbf{r}_k^+ = \mathbf{r}_k^- + K_k \cdot \boldsymbol{\zeta}_k , \quad (4.8)$$

where the weight is defined by the so-called gain matrix  $K_k$ :

$$K_k = C_k^- H_k^T \cdot W_k . \quad (4.9)$$

One notes that since the gain matrix is proportional to the current covariance matrix  $C_k^-$  and weight matrix  $W_k$ , the strongest influence on the estimate will have the measurements with higher weights. By contrast, the estimate, which is already precise, and thus, has a small covariance matrix, will not be changed significantly.

At last, the covariance matrix of the estimate is calculated:

$$C_k^+ = (I - K_k H_k) \cdot C_k^- . \quad (4.10)$$

The algorithm sequentially repeats the prediction and the filtration steps for each of the  $n$  measurements. After filtering the last measurements the vector  $\mathbf{r}_n^+$  — the resulting estimate after all the measurements are filtered is the optimal estimate of the state vector  $\mathbf{r}_n^t$  with the covariance matrix  $C_n^+$ .

However, in real life the evolution of a system  $\mathbf{r}_{k+1}^t(\mathbf{r}_k^t)$  and the model of measurements  $\mathbf{m}_k^t(\mathbf{r}^t)$  dependencies often cannot be described by a linear function. Therefore in order to apply the Kalman Filter method in non-linear cases a procedure of linearization has to be performed.

For example, in the case of a non-linear model of measurements the function  $\mathbf{m}_k(\mathbf{r}_k^t) \equiv \mathbf{h}_k(\mathbf{r}_k^t)$ , the function  $\mathbf{h}_k(\mathbf{r}_k^t)$  needs to be expanded in a Taylor series at the linearization point  $\mathbf{r}_k^{lin}$ :

$$\mathbf{m}_k(\mathbf{r}_k^t) \equiv \mathbf{h}_k(\mathbf{r}_k^t) + \boldsymbol{\eta}_k \approx \mathbf{h}_k(\mathbf{r}_k^{lin}) + H_k(\mathbf{r}_k^t - \mathbf{r}_k^{lin}) + \boldsymbol{\eta}_k, \quad (4.11)$$

where  $H_k$  is the Jacobian of  $\mathbf{h}_k(\mathbf{r}_k)$  at  $\mathbf{r}_k^{lin}$ :

$$H_{k(ij)} = \left. \frac{\partial \mathbf{h}_k(\mathbf{r}_k)_{(i)}}{\partial \mathbf{r}_k(j)} \right|_{\mathbf{r}_k = \mathbf{r}_k^{lin}}. \quad (4.12)$$

In this case the formula to calculate the residual for conventional method (4.5) is changed in the following way:

$$\zeta_k = \mathbf{m}_k - (\mathbf{h}_k(\mathbf{r}_k^{lin}) + H_k(\mathbf{r}_k^- - \mathbf{r}_k^{lin})).$$

In the same manner the non-linear extrapolation equation (4.4a) can be linearized:

$$\mathbf{r}_k^- \equiv \mathbf{f}_k(\mathbf{r}_{k-1}^+) \approx \mathbf{f}_k(\mathbf{r}_k^{lin}) + F_k(\mathbf{r}_{k-1}^+ - \mathbf{r}_{k-1}^{lin}) \quad (4.13)$$

$$F_{k(ij)} = \left. \frac{\partial \mathbf{f}_k(\mathbf{r}_{k-1}^+)_{(i)}}{\partial \mathbf{r}_{k-1}^+(j)} \right|_{\mathbf{r}_{k-1}^+ = \mathbf{r}_{k-1}^{lin}}. \quad (4.14)$$

The Kalman filter equations in the case of a system with non-linear evolution or measurement model is called the extended Kalman filter method. The linearized model differs from the original one, therefore the choice of the linearisation point  $\mathbf{r}^{lin}$  is important. The usual way is to take the current estimator  $\mathbf{r}_k$  as the point of linearization for the  $k$ -th measurement.

Unlike its linear version, the extended Kalman filter in a general case is not an optimal estimator. Moreover, if the initial estimate of the state is wrong, or if the

process is modeled incorrectly, the filter may diverge, owing to its linearization. Having stated this, the extended Kalman filter gives a reasonable performance, and is the standard method for fitting charged particles trajectories in HEP experiments nowadays.

### 4.1.2 Kalman-filter-based track fit for CBM

One of the most important applications of the Kalman filter algorithm in HEP is trajectory fitting in order to reconstruct the parameters of particles produced in collisions. In this case the state vector  $\mathbf{r}$  contains track parameters, the propagation matrix  $F_k$  extrapolates the track from one detector station to the next one in a magnetic field, and the noise matrix  $Q_k$  takes into account multiple scattering due to interaction with the detector material.

In the case of the CBM experiment track fit the state vector of track parameters was chosen in the following form, convenient for a forward detector geometry:

$$\mathbf{r} = \{x, y, t_x, t_y, q/p\}, \quad (4.15)$$

where  $z$ -coordinate is directed downstream the beam along the detector,  $x$  and  $y$  are track coordinates at a certain  $z$ -position,  $t_x \equiv \tan \theta_x$  and  $t_y \equiv \tan \theta_y$  are the track slopes in the  $xz$  and  $yz$  planes, and  $q/p$  is the charge to inverse momentum ratio.

In order to estimate the state vector  $\mathbf{r}$  with the Kalman filter method one needs to define every needed component of the method, namely: initial values of the state vector  $\mathbf{r}_0$  and covariance matrix  $C_0$ , the model of measurements  $H$  and the propagation matrix  $F_k$ , as well as the noise matrix  $Q_k$ .

In the case of the CBM experiment for a secure convergence the initial state vector  $\mathbf{r}_0$  is taken as the estimate of the least squares method using one-component approximation of a magnetic field in the absence of multiple scattering in the detector material.

The model of measurement is supposed to set the relation between the measured detector hits and the state vector. Since the vertex detector of the CBM experiment consists of double-sided strip sensors, each hit measured in the STS consists of two independent one-dimensional measurements — strips. These measurements are linearly dependent on the position of particle in the detector plane.

Thus, the model of measurement  $H$  is linear, namely:

$$H_k = \{\cos(\alpha_k), \sin(\alpha_k), 0, 0, 0\}, \quad (4.16)$$

where  $\alpha_k$  is the strip angle.

The propagation matrix  $F_k$  serves to define the charged particle motion in the non-homogeneous magnetic field  $\mathbf{B}$ . This motion is described as a Lorenz force with the following differential equations:

$$dt_x/dz = c(q/p)t_r(t_y(B_z + t_x B_x) - (1 + t_x^2)B_y), \quad (4.17a)$$

$$dt_y/dz = c(q/p)t_r(-t_x(B_z + t_y B_y) + (1 + t_y^2)B_x), \quad (4.17b)$$

$$t_r(z) = \sqrt{t_x^2 + t_y^2 + 1},$$

here  $B_x, B_y, B_z$  are the field components at a given  $z$  on the particle trajectory,  $c$  is the speed of light. These equations cannot be solved analytically in case of a non-homogeneous magnetic field, since the field components have a complex coordinate dependence. For this reason the standard Runge-Kutta method [81] is used in order to obtain the function  $\mathbf{r}_{k+1}^t = f_k(\mathbf{r}_k^t)$ . Since the  $f_k(\mathbf{r}_k^t)$  dependence appears to be non-linear, the linearization is performed in the same manner as it was shown in (4.4a) at the track point closest to the measurement  $\mathbf{r}_k^{lin}$  giving as a result the desired propagation matrix  $F_k$ .

The next element of the method, which is needed in order to take into account the multiple scattering in the detector material, is the matrix of noise  $Q_k$ . The studies with double sided silicon sensors of 300  $\mu\text{m}$  thickness, similar to the CBM STS sensors, have shown that a minimum ionizing particle, traversing this thickness, creates about 24.000 electron-hole pairs [82]. It means that the particle undergoes at least 24.000 scattering processes, with minimum exchanged energy of 1.8 eV. According to the central limit theorem it makes it possible to describe the total scattering angle of the particle with a Gauss distribution as a sum of a large number of random variables. The width of the distribution is set with the original Highland-Lynch-Dahl formula [83] for the width of the angular distribution:

$$\sigma(\theta) = \frac{13.6 \text{ MeV}}{\beta c p} q \sqrt{L/X_0} [1 + 0.038 \ln(L/X_0)], \quad (4.18)$$

where  $\beta, p$ , and  $q$  are particle velocity, momentum and charge number of the incident particle,  $L/X_0$  is the true path length in radiation length unit. The resulting matrix of noise  $Q_k$  has a following form [84]:

$$Q_k = \sigma_k^2(\theta) \begin{pmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & (t_x^2 + 1)t_r^2 & t_x t_y t_r^2 & 0 \\ 0 & 0 & t_x t_y t_r^2 & (t_y^2 + 1)t_r^2 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix}. \quad (4.19)$$

The energy loss of a particle in thin material of the detector system is small in comparison to the effects considered here and can be neglected.

Historically the Kalman filter implementation was done in a double precision. However, for modern computer algorithms the stability in the single precision becomes particularly important for SIMD calculations and optimal usage of cache memory layered structure. As a result, twofold more data can be stored in the cache and, as well, twice the size of data can later be packed into a SIMD register at double speed. However, the direct switching to a single precision has shown that the 32-bits precision is not sufficient for the Kalman filter track fit and results in numerically unstable behavior of the algorithm. The main obstacle in switching the algorithm from the double precision to the single one, is the discrepancies, that appear due to numerical rounding. As a result one may face poor fit quality, or even physically unacceptable results like negative diagonal elements of the covariance matrix.

The discrepancies can arise during the step of updating covariance matrix when the previous error estimate significantly exceeds the error that must be taken into account while adding new measurement to the estimate. A similar problem is faced while adding the first measurement, where infinite errors for the estimate is replaced by a finite big number.

Therefore the Kalman filter algorithm was modified in order to avoid such instability due to round-off errors. The algorithm single precision stability was increased due to the following changes: the initial state vector estimate is obtained with the least squares fit with magnetic field approximation, a special procedure of updating the covariance matrix in order to increase correction precision and a special procedure of filtering the first measurement [77] are introduced.

### 4.1.3 The track fit quality assurance

While providing the state vector estimate, a very important issue is a proper covariance matrix, which contains estimated errors of the track parameters. In order to study the reliability of parameter error estimation at first, the residuals  $\rho$  of the track parameters, for instance for the  $x$ -coordinate, are calculated as:

$$\rho_x = x^{\text{reco}} - x^{\text{mc}}, \quad (4.20)$$

where  $x^{\text{reco}}$  and  $x^{\text{mc}}$  are the reconstructed and the true Monte Carlo values of the  $x$ -coordinate. A measure of the reliability of the fit are the normalized residual (pull) distributions of the fitted track parameters. Pulls are determined according to the formula:

$$P_x = \frac{\rho_x}{\sqrt{C_{xx}}}, \quad (4.21)$$

where  $C_{xx}$  is the corresponding diagonal element of the covariance matrix, obtained in the track fit. In the ideal case the normalized error distributions of the track parameters should be unbiased and Gaussian distributed with a width of 1.0.

The residuals and the pulls for all track parameters in the CBM experiment are calculated at the first hit of each track. The distributions for the  $x$ ,  $t_x$  and  $q/p$  parameters together with their Gaussian fits are shown on Fig. 7.6 (the results for  $y$  and  $t_y$  are similar). All distributions are not biased with pulls widths close to 1.0 indicating correctness of the fitting procedure. The slight deviations from 1.0 are caused by several assumptions made in the fitting procedure, mainly in the part of the detector material treatment. The  $q/p$  pull is the widest being the most sensitive to these simplifications [73].

The Kalman filter track fit algorithm is used to estimate parameters of the tracks reconstructed in the STS and MVD detectors and their errors for the CBM experiment. The algorithm works stable in single precision and is fully vectorized [77]. The algorithm is also used in order to fit partially reconstructed tracks inside the Cellular automaton track finder while searching for the next hit measurement. It will be shown in the next section, which is devoted to the track finding task.

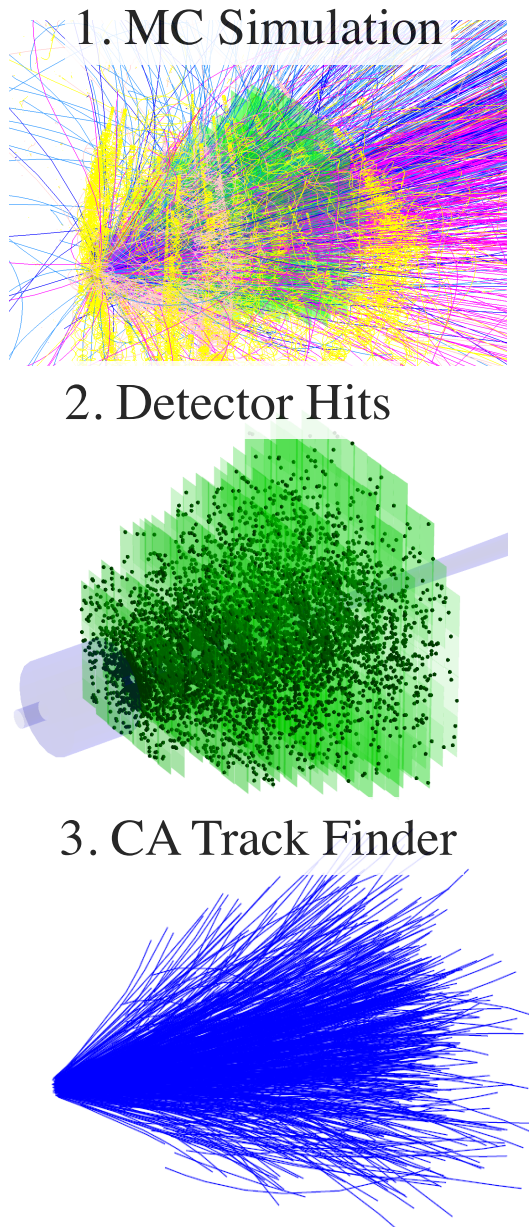

**Figure 4.3:** The residuals and the pulls distributions of the  $x$  ( $43.2 \mu\text{m}$ ,  $1.12$ ),  $t_x$  ( $0.30 \text{ mrad}$ ,  $1.18$ ) and  $q/p$  ( $0.93\%$ ,  $1.32$ ) track parameters, calculated in the position of the first hit inside the CBM STS detector.

## 4.2 Track finding

Since one of the most challenging and time-consuming parts of event reconstruction is track finding, optimization of the track finding algorithm has a great

impact on the computational effort needed for the data-analysis chain in a HEP experiment. Due to the fact that track finding is sometimes required to be done online, the speed of the algorithm plays an important role in experiments and a number of various approaches of track reconstruction methods has been developed in the course of time.

**Figure 4.4:** The illustration of the complexity of the track finding problem: the tracks from a simulated central Au+Au UrQMD collision at 25 AGeV energy in the CBM experiment (top), only hits of the STS as input information for the track finder (middle) and the reconstructed tracks with the cellular automaton track finder (bottom).

The approaches strongly differ from each other as well as the detector systems, which they are used for.

In the next section an overview of several track reconstruction methods will be presented together with their advantages and disadvantages:

- conformal mapping,
- Hough transformation,
- track following,
- cellular automaton.

Due to the noise and impreciseness of detector measurements, a set of hypotheses is usually used in order to improve the efficiency and speed up the track finding process. The possible hypotheses are the track model, track seeds from other detectors and the position of track origin (for example, target region).

As far as the track model is concerned, the tracking methods can be classified as global or local. The global methods need to treat all the measurements simultaneously, usually using the track model, while the local methods go through the measurements one by one. In other words, the global methods have to consider all the available measurement information while accepting or discarding a certain track and local methods make such decisions based only on a subset of the measurement information. Examples of global approaches considered below are conformal mapping, Hough transform, while the track following and cellular automaton methods are regarded as local.

The methods drastically differ in their approach, usually making a direct comparison difficult. Thus, usually experiments try to develop various methods in the beginning and later decide upon the best one for the certain detector system and the physics case. Let us consider some methods, which CBM tried to apply for the track finding in the STS detector.

## 4.2.1 An overview of the track reconstruction methods

### Conformal mapping

One of the standard global track reconstruction methods is Conformal mapping [85], which is used in the presence of a uniform magnetic field. The main idea of the method is to simplify the event pattern by applying a map, which transforms the circular tracks of charged primary particles in a uniform magnetic

**Figure 4.5:** The conformal mapping method for the track reconstruction task in CBM: original tracks in real space (top) and straight tracks after conformal transformation (bottom) [86].

field into straight lines in a conformal space (Fig. 4.5). The conformal transformation used for this task transforms coordinates from measurement space  $(x, y)$  into conformal space  $(x', y')$ :

$$x' = \frac{x - x_0}{(x - x_0)^2 + (y - y_0)^2}; \quad (4.22)$$

$$y' = \frac{y - y_0}{(x - x_0)^2 + (y - y_0)^2}. \quad (4.23)$$

Since reconstructing a straight line is much easier than searching for a circle, in the conformal space these lines can be easily found with histogramming. However, the form of the transformation immediately reveals the first obstacle of the method: the transformation requires knowing in advance the position of the primary vertex  $(x_{pv}, y_{pv})$ . This problem is usually avoided by assuming a common vertex with coordinates  $(0;0)$ , which will turn the transformation equations into:

$$x' = \frac{x}{x^2 + y^2}; \quad (4.24)$$

$$y' = \frac{y}{x^2 + y^2}. \quad (4.25)$$

However, this simplification does not help to generalize the method for the search of secondary tracks. Further simplification is done by assuming a uniform magnetic field, which is not true for a general case.

Despite the disadvantages, the conformal mapping method can be successfully applied for the search of primary tracks in a simple event topologies, where it can have a simple and fast implementation in hardware.

### Hough transform

One more example of a global track finder algorithm is the Hough Transform [87]. This method converts the measurements from a real space  $(x, y)$  into the parameter space  $(a, b)$ . Fig. 4.6 illustrates the example when the measurements of the curved track, described by two parameters — track curvature and emission angle, are plotted in the parameter space, providing as a result the intersection point of the initial track parameters. Let us consider the simplest case of a straight track:

$$y = a \cdot x + b. \quad (4.26)$$

In this case the transformation is:

$$b = -a \cdot x + y. \quad (4.27)$$

Thus, a certain position measurement in the detector plane  $(x_i, y_i)$  represents a straight line in the parameter space  $(a, b)$ . Together several such measurements of one initial track are transformed into a set of lines in the parameter space intersecting in the cluster region, which is usually localized in the algorithm with a simple histogramming.

**Figure 4.6:** The Hough transform method for the track reconstruction task: original track in the real space (left side) and straight lines in the parameter space, corresponding to certain data points on the initial trajectory (right side).

The obvious limitation of the method arises from the need of a global track model for the stage of transformation to the parameter space. However, even in the case where an analytic global track model exists, usually it is a simplification, since it cannot include the effects of multiple scattering or inhomogeneities of a magnetic field. Also it is hard to obtain track errors in the case of the transformation. When it comes to hardware implementation, the memory bandwidth usually limits the implementation due to the need for multidimensional histogramming. In case of the CBM experiment the biggest obstacle with the Hough-transform-based track finder (Fig. 4.7) was the memory issue, since the algorithm required about 1.2 GB of RAM for the Hough-Space, otherwise it took 15 minutes due to memory swapping [88].

### Track following

An example of a very intuitive local method of track reconstruction (Fig. 4.8) is track following [89]. As the name suggests, the main idea of the method is the prediction of the position of the initial track in the next consecutive detector plane, assuming a certain local model of track propagation in the detector volume.

**Figure 4.7:** One 2-dimensional Hough plane filled with transformed hits [88]. A central plane processing the hits near the beam pipe is shown here. There are seven peaks in the histogram (black points), corresponding to the seven particle tracks found. A peak is defined by more than three hits in consecutive detector layers. Six peaks can be assigned to certain MC tracks. The lower most peak does not correspond to any real track.

The prediction is checked by searching for registered hits in a certain corridor region around the predicted position. The width of the corridor is chosen with respect to the detector measurement precision and a possible multiple scattering effect due to detector material budget.

**Figure 4.8:** The 3D track following method for CBM. Prediction and search in  $XoZ$  and  $YoZ$  projection [88].

Most HEP experiments in the beginning needed an ideal Monte Carlo track finder, which could collect reconstructed hits into tracks using Monte Carlo information. Based on such an ideal track finder it is very easy to implement a realistic track following.

However, there are certain limitations, which made the method not applicable

in certain cases. First of all, the algorithm is featured with an exponential growth of combinatorial combinations to be considered with increasing track multiplicity. Thus, the algorithm can work efficiently within a reasonable time only up to a certain hit density. Another issue is raised, when it comes to implementation of the algorithm on the compute devices. The problem is that the algorithm realizes a random memory access, while checking different next possible hits on the track. This random memory access usually becomes a bottleneck for a program implementation, due to the slow speed of such operations. Moreover, if one tries to examine the logic of the approach, it is easy to see that during the search the algorithm often has to repeat certain calculations several times, since some of the results get discarded.

In the early stages of the CBM experiment, when the STS detector was still planned as a pixel detector, the track following method was tested for the reconstruction routine (Fig. 4.8). The track reconstruction procedure was accomplished in 3D space on both  $x$ - $z$  and  $y$ - $z$  projections simultaneously [88]. The procedure alternated between both views, predicting a track position on the next station and searching for hits in the vicinity of the predicted position.

Starting from the middle of the target area, this point was sequentially connected with all hits in the first station in  $y$ - $z$  view, where tracks were close to straight lines. The straight lines driven via these two points were prolonged to the plane of the second station. All hits in an asymmetrical corridor around the intersection point were then used for fitting a parabola in  $x$ - $z$  view which is prolonged to the next station. Since several prolongations could happen, corridors were set around each point predicted on the third station. A similar corridor was set in the  $y$ - $z$  view on the third station. If hits were found within these limits, they were attached to the track.

When the STS detector was redesigned using double-sided strip detector modules, most of the methods could not cope with the increased number of hits and, as a result, more intensive combinatorial search.

### **Cellular-automaton-based track finder**

As was shown, one of the major obstacles to be solved by each track finder is a huge and growing fast with track density amount of combinatorial combi-

nations, which track finder has to consider in order to bind together one- or two-dimensional measurements into five-dimensional tracks. Unfortunately, the exponential growth of the combinatorial enumeration at high track densities usually makes it impossible to consider all combinations within a reasonable time frame. The CBM experiment can serve as a proper illustration of this problem, since the experiment has tried different tracking approaches for the planed pixel version of the STS detector. Unfortunately, most of them could not work anymore due to increased combinatorial combinations after switching from pixel to double-sided strip version of the STS.

However, a solid solution for combinatorial optimization was provided by the CA track finder algorithm. The CA track finder can be regarded as a local version of the Hopfield neural network [90] and will be discussed in detail in the next section.

### 4.2.2 Cellular automaton

Although the idea of everything being made up of large numbers of discrete elements was discussed around 450 BC by Leucippus and Democritus, it was still a long time before abstract idealizations like cellular automata were introduced. In 1967, Konrad Zuse also suggested that the universe itself is running on a cellular automaton or a similar computational structure. In 1969, he published the book “Rechnender Raum” (Calculating Space) [91]. He proposed that the physical laws of the universe are discrete by nature, and that the entire universe is the output of a deterministic computation on a single cellular automaton. This idea has attracted a lot of attention, since there is no physical evidence against Zuse’s thesis. “Zuse’s Theory” became the foundation of the field of study called digital physics.

The concept of cellular automaton as we know it today was originally proposed in the 1940s by Stanislaw Ulam and John von Neumann in an attempt to develop an abstract model of self-reproduction in biology, which eventually led to the name “cellular automata”. After John Conway introduced his Game of Life [92], the method became popular and, despite its biological name, in the course of time the method accrued range of applications in computer science, mathematics,

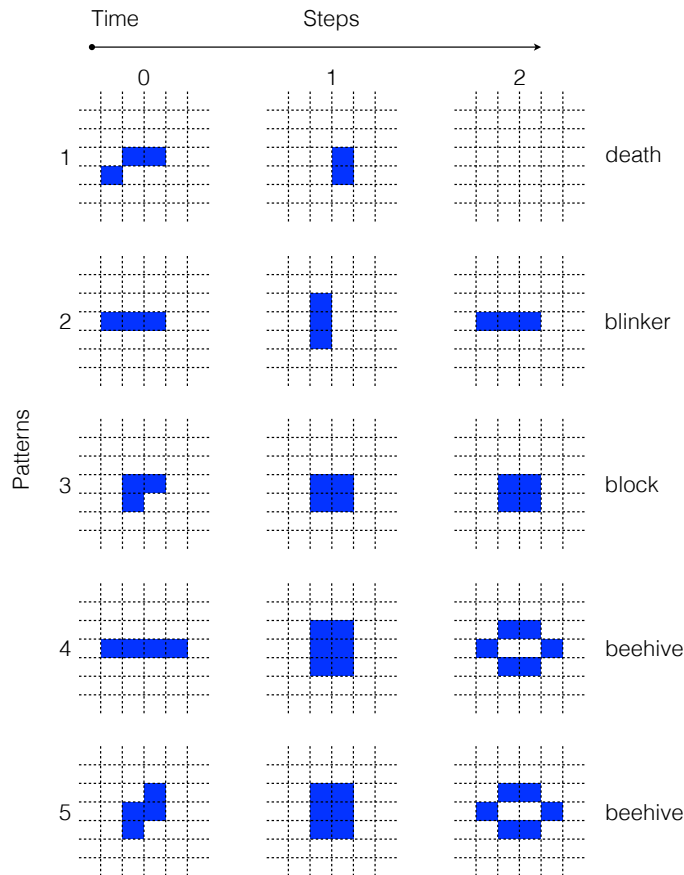

physics and chemistry.

The cellular automaton method models a discrete dynamical system, whose evolution is completely determined by local mutual relations of constituent elements of the system. The described system must be expressed as a grid of elements, called “cells”. Each element at a certain step takes one of a finite number of states, such as “on” and “off”, for instance. Usually the system is homogeneous, which means that all cells are treated the same way and the neighborhood definition is the same for all cells. Only cells from their own neighborhood have a direct influence on the cell state at the next step. An initial state is generated by assigning a state to each cell. At the next time step the evolution of the system is defined according to some fixed set of rules (generally, mathematical functions) that define the new state for each cell based on the current state of the cell and the states of the cells in its neighborhood. Typically, the rule for updating the state of cells is the same for each cell and does not change over time, and is applied to the whole grid simultaneously, though exceptions are known, such as the stochastic cellular automaton and asynchronous cellular automaton.

The most famous and very illustrative example of the cellular automaton algorithm is Conway’s Game of Life. The universe of the Game of Life is an infinite two-dimensional orthogonal grid of square cells. Each of cells is in one of two possible states, alive or dead. Every cell interacts with its eight neighbors, which are the cells that are horizontally, vertically, or diagonally adjacent. The evolution at the next step is defined by the following rules:

- any live cell with fewer than two alive neighbors dies of isolation at the next step,
- any live cell with two or three live neighbors stays alive at the next step,
- any live cell with more than three live neighbors dies of overpopulation at the next step,
- any dead cell with exactly three live neighbors gets born and stays alive at the next step.

Despite being a simple mathematical abstraction the cellular automaton system exhibits the sophisticated feature of self-organization. Even starting from a chaotic initial condition, the system organizes some typical structures, like the

**Figure 4.9:** The simple structures produced in the evolution of Game of Life. Some structures, like pattern 1, die out in the next generation. Some structures, like pattern 2, are called oscillator and repeat its form each second generation. Some structures, like patterns 3, 4, 5, create stable colonies.

ones shown in Fig. 4.9. Some of these structures are sentenced to die out, some of them obtain a stable state or represent looped structures (like blinkers).

This interesting feature of self-organization makes the method applicable for the track reconstruction problem. It can be regarded as a local version of recurrent neural network. Moreover, due to the locality, cellular automaton methods are highly suited for parallel approaches. Thinking of a computer program for such a model, every cell can be calculated by an independent thread, and on top of that the data exchange between the threads is restricted to those threads processing adjacent cells. For track finding application the method first time was used to suppress noise hits in the event reconstruction for the ARES experiment [98].

This application is considered in the details in the next section.

### 4.2.3 Cellular-automaton-based track finder

Different versions of the cellular-automaton-based track finder were successfully applied in a number of HEP experiments like ARES<sup>1</sup> [93], ALICE, HERA-B [94], K2K [95], LHCb<sup>2</sup> [96], NEMO<sup>3</sup> [97], STAR and future CBM. All the above mentioned versions were adjusted to certain detector systems, and thus may be essentially different from the original cellular automaton concept. However, the first cellular-automaton-based track finder for the ARES experiment was actively exploiting the original idea of CA in order to suppress the noise and restore the missing clusters due to the detector malfunction.

**Figure 4.10:** The cellular automaton method for the tracking algorithm in the ARES experiment is similar to the Game of Life. The target is placed in the center. It is surrounded by 12 coaxial cylinder wire chambers. The clusters produced by reconstructed tracks are shown with blue circles. The clusters killed in the algorithm evolution are shown as red crossed circles. They should belong to noise clusters,  $\delta$ -electrons and clusters produced by the track scattered on the detector wall [98].

Indeed, the way ARES track finder was filtering out the noise measurements was very similar to the Game of Life evolution. The discrete nature of the Multi-Wire Proportional Chamber (MWPC) allows the consideration of clusters (continuous group of hired wires) as living cells. The dead cells are the empty ones,

<sup>1</sup>Automotive Research Experiment Station

<sup>2</sup>Large Hadron Collider beauty experiment

<sup>3</sup>Neutrino Ettore Majorana Observatory

which contain no hits. As a rule, each living cell may either belong to a real track or represent noise, each dead one may either belong to no track or be a missed hit due to detector inefficiency. The main idea of CA tracking is to exploit the concept of CA evolution in order to kill all noise living cells and restore the missing ones forming real tracks.

The neighborhood of the cluster was defined as the region in the adjacent chambers, where the track, which caused the cluster, could potentially pass. Each cell belonging to a real track should have from 2 up to 4 neighbors. Having stated this, the tracking algorithm should get rid of noise cells, which have more than two neighbors, and restore missed cells, whose neighbors have less than 2 neighbors. To prevent suppression of tracks from the ends, imaginary chambers before the first and after the last chamber were assumed as containing the needed neighbors for the cells on the outer stations. The evolution was calculated in two steps: first giving birth to the new cells and after killing the dead ones. The birth and death steps are performed several times until a stable or cyclic state is achieved. As a result the algorithm (Fig. 4.11) allows the suppressing of 65%–70% of noise hits and decreases the volume of data to be processed by a factor of 3.

**Figure 4.11:** Distribution of the number of events according to the number of clusters in an event before processing with CA algorithm and after (bold line). After the algorithm evolution one can clearly see the picks, corresponding to one-, two-, and three-tracks collisions [98].

The initial CA-based track finder is suited for the ARES experiment and worked successfully in that conditions. However, it needs major changes in order to be applied to a detector with significantly higher track multiplicities. The first step towards adapting the algorithm for a dense track environment is redefining

the cell concept. The cell should reflect as many parameters of its track as possible. In the ARES experiment the cluster was defining position and direction of the track. The situation changes if we consider other detector type like pixel or strip detector, which provide spatial information only. Thus, one measurement alone is not able to provide sufficient information about track parameters in this case. The knowledge on the track parameters, contained by the cell, can be improved, if we combine several consecutive detector measurements into one cell.

**Figure 4.12:** The simplified illustration of the cellular automaton based track finding algorithm. Here the tracking stations are shown by the vertical dashed lines, hits of two different particles are shown by the blue and green circles, the noise hit is shown by the empty circle. Track segments are shown by the solid lines with their thickness and color corresponding to a possible position of a segment on a track.

The general scheme of the CA-based track finder in the case of a cell with a higher dimensionality is shown in Fig. 4.12. In this example the cell is a potential track segment, consisting of two detector measurements. The algorithm

starts with detector measurements (hits) as input information. In the simplified illustration the detector stations are shown with a dashed line, the blue hits were produced by one particle, the green ones — by the other one, while the white hit represents the noise. At the first stage the algorithm builds all possible track segments before going into the main combinatorial search (1). After this stage is finished the CA track finder never goes back to processing hits information again, working only with created track segments instead.

After the cells were formed, the evolution of the cellular automaton takes place. Taking into account the track model, the method searches for neighboring segments, which share a hit in common and have the same direction within some error, and, thus, potentially belong to one track. During this search the track finder also estimates a possible position of the segment in the track (2). Beginning with the first station the track finder goes to the last station moving from one neighbor to the next assigning to each segment a counter, which stores the number of neighbors to the left. Starting with a segment of the largest position counter, the track finder follows a chain of neighbors collecting segments into a track candidate (3). As a result one gets a tree structure of track candidates. In the last stage (4) the competition between the track candidates takes place: only the longest tracks with the best  $\chi^2$ -value sharing no hits in common with better candidates are to survive.

Thus, the increased track multiplicity forcing the cell to combine several measurements also changes the purpose of the evolution stage of the algorithm. In the initial one-measurement case the aim was to resolve the measurements from different tracks from each other. In the high track multiplicity case it is not possible, and the main aim of evolution phase is to simplify the track construction process.

As one can conclude from the CA track finder strategy, the major part of the algorithm is intrinsically local, since it is working only with data within a small neighborhood region at each particular moment. In addition to that, the algorithm transforms the tracking information step-by-step to a higher consolidation extent: moving from hits to segments, from segments to candidates, from candidates to tracks. Thus, the information processed and analyzed once by the track finder is stored in a new form for the next stage with no need to read it again

later. This optimizes memory access, since no data is read or processed twice. These algorithm features make it suitable for parallel implementation on modern many-core CPU/GPU computer architectures.

Different variations of this scheme were applied in HEP experiments with high track multiplicity. In the next section details of the CA-based track finder algorithm for the CBM experiment are discussed.

#### 4.2.4 Cellular automaton track finder for CBM

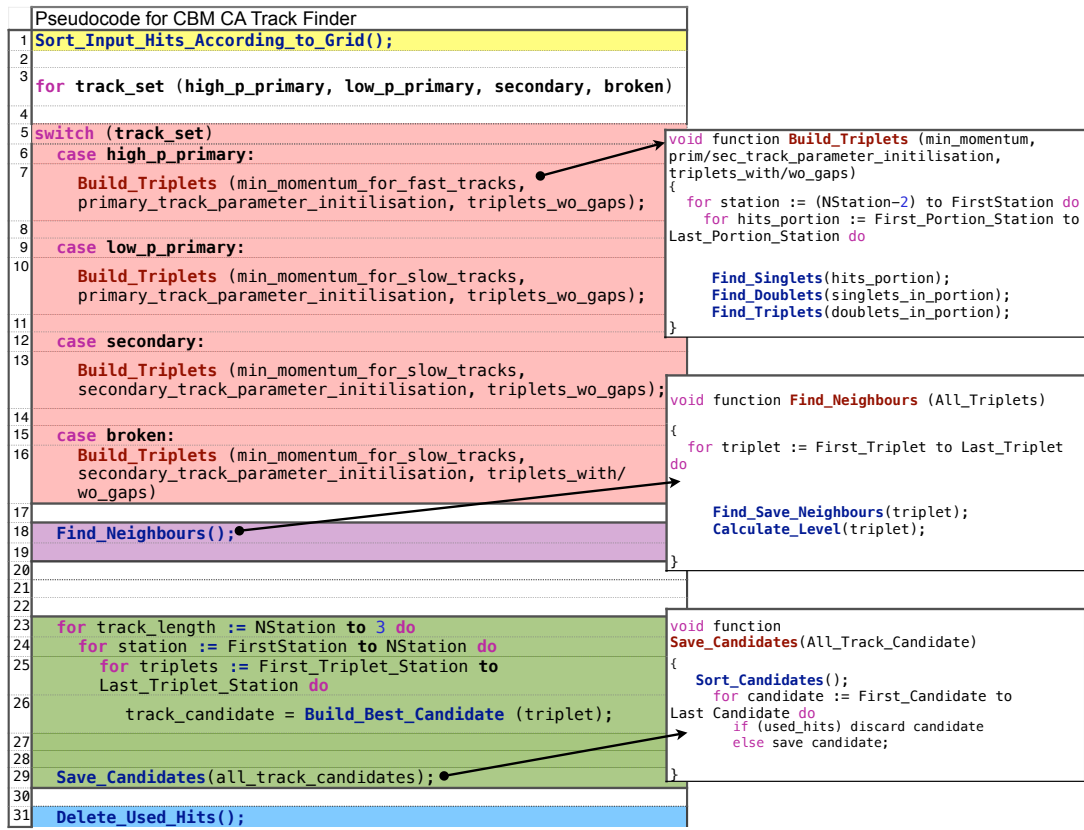

The CA method's features made the algorithm an appropriate solution for the track reconstruction in the CBM main tracking detector STS. Let us consider in detail the CBM version of the CA track finder.

A charged particle track in a magnetic field has 5 degrees of freedom. Hence, a particle trajectory can be fully described with five parameters. The CBM state vector was chosen in the following form:  $(x_i, y_i, t_{xi}, t_{yi}, q/p)$ . Here,  $x_i, y_i$  are the coordinates of the point where the particle intersects the plane of the  $i$ -th STS detector;  $t_{xi}, t_{yi}$  are the slopes of the track to the  $OZ$ -axis; and  $q/p$  is the particle charge to momentum ratio.

Let us define the triplet as a group of 3 hit measurements on adjacent detector stations, potentially produced by the same particle. Since hit includes  $(x_i, y_i)$  — two measurements of intersection of a particle with a certain detector plane, the triplet represents the set of 6 coordinate measurements and allows the unique determination of all five parameters of a reconstructed track segment. For this reason in CBM the cells of the CA track finder are triplets.

The triplet parameters coincide with the track parameters:  $(x_i, y_i, t_{xi}, t_{yi}, q/p)$ . It gives the opportunity to estimate the  $\chi^2$  deviation between the hit measurements and the parameters of reconstructed track segments with the Kalman filter method. Such strategy has proved that already at the triplet level most random 3-hit combinations can be rejected according to the  $\chi^2$ -value, since they are unlikely to represent a segment of a real track.

The strategy of the algorithm can be explained with the help of the pseudocode scheme, which is shown in Fig. 4.13. The actual tracking procedure starts with initialisation ( Fig. 4.13: pseudocode line 1). At this stage the algorithm allocates

**Figure 4.13:** A pseudocode scheme for the CA track finder algorithm.

memory for the input information and prepares a special data structure to store hits — the grid (Fig. 4.14).

The grid structure plays an important role for the speed of the algorithm, since it provides fast access towards hits for the most time-consuming part of triplets construction. While binding hits into triplets, one often faces a task of finding a hit of the triplet in the certain spatial area of a station. In order to do it quickly, a regular 2D grid is introduced on each station, with the cell size inversely proportional to the hit density on the station. All hits are sorted and stored in the memory in the order of their cell numbers. For each cell the pointer to the first hit in this cell is stored.

The idea of grid approach is illustrated in Fig. 4.14. After extrapolation of the track segment to the next station, the algorithm obtains the estimated position  $(x, y)$  with extrapolation errors. It defines a certain region of interest on the station, where potentially the next hit can be located. In order not to go through

**Figure 4.14:** The grid structure for one STS station provides fast access towards the hit measurements in the area of track extrapolation within the extrapolation errors.

the whole list of hits on the station and check whether they lay in the region of interest, one can use the grid structure.

After defining the region of interest, the algorithm builds a special object — HitArea, which is defined by the area of bins fully covering the region of interest (shown with blue square in the figure). The grid structure allows a fast access towards the hits laying within the HitArea. Since the grid stores indexes of the first hits in the bin for each bin, to check all the hits in the HitArea, the algorithm just needs to check several groups of hits, sorted and located locally in the memory, instead of going through the whole list of hits on the station. In this example, it would be:

- starting from 1st hit in bin 7 until 1st hit in bin 10,
- starting from 1st hit in bin 12 until 1st hit in bin 15,
- starting from 1st hit in bin 17 until 1st hit in bin 20.

This approach allows for quick identification of hits in a certain area of the station, since they are located close to each other in the memory and the grid structure instantly provides indexes of desired hits.

The most time-consuming part of the algorithm (90.4% of the total time) is the triplet building stage. Triplets are built out of hit measurements, which can potentially belong to the same track. Since the tracking algorithm is designed for online reconstruction, the algorithm speed plays a crucial role and a lot of optimi-

sation efforts were devoted to speed up the execution. One of such optimisations come into play in the very beginning.

The Monte Carlo simulation has shown that the major part of the particles of the particular physics interest come from the region of the primary vertex with momentum greater than  $0.1 \text{ GeV}/c$ . Knowing in advance that the particle is emerging from the primary vertex with a large momentum, drastically improves the time needed to reconstruct such a track, due to a better initial track parameter initialization and a small curvature of the track. These observations have led to the decision to split the reconstruction procedure into several stages, in order to perform fast and computationally easy parts at first and suppress the combinatorial enumeration for later stages.

Thus, the CA track finder consists of the following stages (pseudocode line 3):

1. the search for tracks from fast ( $p > 1 \text{ GeV}/c$ ) quasi-primary (emitted from the target region) particles,
2. the search for tracks from slow ( $0.1 < p < 1 \text{ GeV}/c$ ) quasi-primary particles,
3. the search for tracks from secondary particles with arbitrary momentum,
4. the search for tracks with a missed hit on a station.

For each set of the tracks the same procedure is repeated with different initial parameters and a different set of cuts. After each stage, the input hits included in reconstructed tracks are tagged as used and removed from consideration in the next stage. This approach suppresses possible random combinations of hits and improves the speed of the algorithm at high track multiplicities.

After the type of initial triplet parameter initialization (for the primary or secondary track search) and cut values (for the large or small momentum track search) are defined by setting the desired track type (pseudocode line 3), the actual triplet building procedure is to begin (pseudocode lines 5–16). Triplets are built station by station, moving upstream starting from the sixth station to the first station.

In the beginning in order to use SIMD registers, all input data is packed in single precision SIMD vectors, so that all calculations later are vectorised. For the reasons of memory optimization all hits on each station are split into portions of  $N$  hits.  $N$  here is a number divisible by the number of elements in the SIMD

**Figure 4.15:** The illustration of three types of triplets built by the CA algorithm: 1) with the second hit missing 2) with the third hit missing 3) with no missing hits (left side). Two neighboring triplets, combined into a track (right side).

register, since the hits are processed in a SIMD-ised manner.

Each triplet is build in 3 steps: to the starting hit consecutively second and third hits are added, rejecting non-physical combinations according to the local track model at each step. Thus, at first each hit on the station is considered a starting hit of the triplet. To the starting hit we add the target with some errors, this way obtaining a certain spatial direction. This structure is called singlet.

The singlet together with its errors is extrapolated to the next station, taking into account track model and possible multiple scattering. While searching for the next hit on this station, the algorithm creates a new HitArea object. All hits within the hit area potentially belong to the same track as the singlet hit does. Adding each hit from the hit area to the singlet, one obtains an array of doublets. The doublets are fitted with the Kalman filter method and some of them are rejected due to high  $\chi^2$ -value. In same manner each doublet is propagated to the next station and the array of triplets for the starting hit is obtained. The major part of random combinations are rejected due to  $\chi^2$ -value after adding the third hit to triplets.

Out of triplets discussed above one can construct tracks with consecutively registered hits in each station only. However the detector inefficiency may lead to the fact that some hits cannot be registered. In this case a hit on a certain

station will be missing. In order to make the algorithm more stable towards detector inefficiency there is one more additional stage of building triplets with one hit missing (Fig. 4.15). This way we introduce two additional categories of triplets:

- with hits on  $k$ -th,  $(k + 1)$ -th and  $(k + 3)$ -th stations
- with hits on  $k$ -th,  $(k + 2)$ -th and  $(k + 3)$ -th stations,

where  $k$  — is the starting station number. Since the probability of having two hits missing in the raw in the track is less than 0.05%, nearly all tracks can be reconstructed with this approach. After all triplets are constructed including the ones with missing hits, they are copied to one general array.

Now the triplets should be grouped into track candidates. Since the momentum is conserved in a magnetic field, in order to find triplets potentially belonging to the same track, one needs to take into account all five state vector parameters. Such so-called neighboring triplets should coincide in position, slope and momentum. The easiest way of fulfilling this requirement is to define neighbors as the triplets, sharing two common hits and having the same momentum within estimated errors (Fig. 4.15). Thus, as the next step the algorithm loops over all triplets and finds and stores for each one the list of possible neighbors according to this definition.

In order to further simplify the procedure of combining triplets into tracks, one can also estimate the position of the triplet in the track. It is done with the help of, so-called, level, which is calculated for each triplet during the search for neighbors. The level of a triplet is defined as the length of the longest continuous chain of neighboring triplets in the direction to the target. The level of a triplet helps to locate the triplet on the track: the greater the value it takes, the longer track can be potentially constructed with a certain triplet.

Having estimated the possible position in the track, the triplets can be easily connected into a candidate tracks (pseudocode lines 23–26). The main aim of this procedure is to build the best set of tracks according to  $\chi^2$ -value, that share no hits in common. It allows suppressing of random combinations of triplets. If two track candidates share a hit in common, the preference is given to the longest track, since the probability of a random hit combination to represent the track

model decreases exponentially with the number of hits.

Thus, the procedure of constructing tracks is designed in such a way, that it starts with building the longest tracks first. Their hits are tagged as used and removed from consideration. After the longest tracks are found, the algorithm consecutively searches for tracks with one hit less and so on until the primary tracks with 3 hits only.

Starting with the triplets with the maximum level, the chain of neighbors with a level consecutively descending by one is connected into track candidates. A treelike structure of potential track candidates is formed in this manner, from which the best track is selected according to the  $\chi^2$  criterion.

Having all the candidates of a certain length constructed, the algorithm sorts them according to their  $\chi^2$ . After this procedure is finished, candidates one by one sequentially are checked to contain used hits. If at least one used hit is found, the candidate gets discarded, if not — the candidate is stored (pseudocode line 29).

After the stage of track reconstruction for the current set of tracks is finished, the final stage of the algorithm takes place (pseudocode line 31): all the hits used in the reconstructed track are removed from the input information for the next stage.

### 4.2.5 Track finding performance

In order to quantify the performance of track finding methods, one needs to introduce a formal definition of efficiency. Usually the reconstruction efficiency is defined as the number of successfully reconstructed tracks as a fraction of all possible tracks of interest. Thus, for a quantitative definition of efficiency, one needs to define a criterion whether a certain particle has been reconstructed together with a definition of tracks of interest.

First of all let us define tracks of interest, which potentially can be reconstructed with a certain detector system. On one hand, this definition should be driven by the physics motivation of the experiment. In order to reconstruct the momentum of a charged particle one needs at least three hits, otherwise there are not enough measurements to define all track parameters. Thus, there is no sense in reconstructing tracks shorter than three hits.

On the other hand, these tracks of interest should be potentially reconstructable with a certain detector system. This way one excludes the detector acceptance from the efficiency definition, so that one can compare pure algorithm reconstruction efficiency for different detector systems.

In the case of CBM collisions at 25 AGeV beam energy simulated by UrQMD have shown that track multiplicity in the STS and the MVD detectors is so high that it leaves no possibility of distinguishing between secondary tracks with three hits and random combinations of three hits. Also for a particle with momentum lower than 0.1 GeV/ $c$  the multiple scattering in the detector material is so strong, that it is not possible to reconstruct such a distorted track shape. Taking these aspects into account, in CBM the track is called reconstructable if it has crossed at least four consecutive STS stations and its momentum is higher than 0.1 GeV/ $c$ .

Now let us introduce a criterion, whether a certain particle has been reconstructed or not. There are two generally accepted concepts [99]:

*Hit matching:* the method analyzes the origin of each hit in the reconstructed track using the Monte Carlo information. If the majority of hits originates from the same particle (not less than some definite fraction of hits was caused by this particle), the track is called reconstructed. The exact fraction is defined in such a way, that the reconstructed track parameters are still not affected significantly, if the track has not more than some percentage of wrongly attached hits. Experience has shown that in the majority of cases if at least 70% of hits belong to the same particle, the reconstructed track parameters allow for correct physics analysis. This method is stable in the limit of very high track densities, but it requires the Monte Carlo information.

*Parameter matching:* The reconstructed parameters of a track are compared with those of the Monte Carlo simulated particle. If the parameters agree within certain errors (for example,  $3\sigma$  around the true Monte Carlo particle parameters), the track is called reconstructed. This method requires less functionality from the simulation chain. It bears the danger of accepting random coincidences between true particles and artifacts from the pattern recognition algorithm. In extreme cases, this can lead to the paradox impression that the track finding efficiency improves with increasing hit density.

The efficiency is defined as the ratio between reconstructed  $N_{reco}$  and recon-

structable tracks  $N_{accept}$ :

$$\varepsilon = \frac{N_{reco}}{N_{accept}}. \quad (4.28)$$

Since both hit and parameter matching concepts require Monte Carlo data, they cannot be applied in case of real data. For real data the efficiency evaluation is tricky, but can be performed under certain conditions if at least two independent track finders are available.

In this case the efficiencies of the track finder are uncorrelated and under the assumption of the absence of wrongly reconstructed tracks, which were not produced by any particle, the efficiency of one procedure can be determined by the fraction of its own tracks among the tracks, found by the other procedure [100]: If  $N$  is the total number of tracks, then:

$$N_1 = N \cdot \varepsilon_1, \quad (4.29)$$

where  $N_1$  is the number of tracks reconstructed by the 1-st track finder.

$$N_2 = N \cdot \varepsilon_2, \quad (4.30)$$

where  $N_2$  is the number of tracks reconstructed by the 2-st track finder.

$$N_{12} = N \cdot \varepsilon_1 \cdot \varepsilon_2, \quad (4.31)$$

where  $N_{12}$  is the number of tracks reconstructed by both track finders. These equations allow determination of the unknown efficiencies of both track finders.

However, since the CBM experiment is not operating yet, it works with simulated data and uses the hit matching version for definition of the reconstructed track. A reconstructed track is assigned to a generated particle, if at least 70% of its hits have been produced by this Monte Carlo particle. If the particle is found more than once, all additionally reconstructed tracks are regarded as clones. A reconstructed track is called a ghost, if it cannot be assigned to any generated particle according to the 70% criterion.

The probability of reconstructing a certain particle strongly depends on its parameters, mostly momentum and the point of origin. Fast particles with large momentum usually have straight trajectories and are almost not influenced by the multiple scattering. On the other hand, low momentum particles not only

**Figure 4.16:** Track reconstruction efficiency as a function of track momentum and track finder performance after the search for primary tracks with high momentum.

have more curved tracks and get randomly scattered in the detector material, but also often leave the detector volume after a few stations. Thus, a small number of hits also complicates the task of track reconstruction in this case. As far as the point of origin is concerned, primary tracks have the advantage of the additional measurement over secondary tracks — the target.

In order to better analyze the performance of the CA track finder, the efficiency is calculated for different sets of tracks. First of all, the tracks are divided into two momentum sets: high momentum ( $p > 1 \text{ GeV}/c$ ) and low momentum ( $0.1 \text{ GeV}/c < p < 1 \text{ GeV}/c$ ) tracks. Secondly, the tracks are divided into primary tracks and the tracks, originating from short-lived particles' decay points.

Let us briefly go through the list of four CA track finder iterations, outlining the initialization parameters used and the efficiency performance achieved after each of them.

In the very first stage the algorithm searches for high momentum primary tracks. Since searching for almost straight tracks origination from the primary vertex is relatively easy due to smaller extrapolation errors and, thus, less combinatorics, this iteration is relatively fast and supposed to suppress combinatorics for later search.

The parameters, used in the stage for track estimate initialization, reflect the

**Figure 4.17:** Track reconstruction efficiency as a function of track momentum and track finder performance after the search for primary tracks with low momentum.

desired track category. The initial track position and errors in the covariance matrix for the propagation in the magnetic field are defining the target area:  $x = 0$ ,  $y = 0$ ,  $\Delta x = 0.01$  cm,  $\Delta y = 0.01$  cm, which corresponds to a primary track. The initialization of  $q/p$  track parameter is set to zero, since one does not know in advance the sign of particle charge, while the  $\Delta q/p$  in the covariance matrix is set to the value, which corresponds to the track with momenta of about 0.5 GeV/ $c$  making the propagation errors relatively small.

As a result, the track finding performance after the first iteration is presented in the table in Fig. 4.16. As one can see, since the parameter initialization is tailored to reconstruct primary tracks with high momentum, the efficiency for the reconstruction of this category of tracks is of high value — 94.9% already after the first iteration, while the reconstruction of low momenta and secondary tracks is not sufficient.

In Fig. 4.16 the track reconstruction efficiency dependence as a function of track momentum is illustrating that the first iteration, due to parameter initialization used, is able to reconstruct tracks with momentum above 0.5 GeV/ $c$ .

The main aim of the second iteration is to include the search for low momenta primary tracks as well. That is the reason why  $\Delta q/p$  in the covariance matrix is initialized with 10 times higher value during this iteration. It corresponds to

**Figure 4.18:** Track reconstruction efficiency as a function of track momentum and track finder performance after the search for secondary tracks.

the track with momenta until about 0.15 GeV/ $c$ , making the propagation errors larger. All other parameters are used with no change at this point.

The resulting performance can be found in the table in Fig. 4.17. After the second iteration, the reconstruction efficiency for the low momenta primary tracks has increased from 56.8% to 91.4%. However, the ghost and clone rate get increased as well due to increased combinatorics.

Also, the effect on the reconstruction efficiency as a function of momenta dependence in Fig. 4.17 is noticeable, since after the second iteration the algorithm is able to reconstruct tracks with momenta until about 0.1 GeV/ $c$ .

The third iteration is targeted to the search for secondary tracks. In order to include the secondary tracks in the consideration the initial parameter initialization of position errors in the covariance matrix in this case is 10 times larger:  $\Delta x = 0.1$  cm,  $\Delta y = 0.1$  cm.

If one compares the track finder performance after the iterations with the search for primary tracks with performance after the third iteration (Fig. 4.18), one observes the improved reconstruction efficiency of secondary tracks: from 84.5% to 86.6% for high momenta tracks, and from 54.2% to 54.7% for low momenta tracks.

In the last iteration the algorithm searches for the tracks with hits not reg-

**Figure 4.19:** Track reconstruction efficiency as a function of track momentum and track finder performance after the search for tracks with missing hits due to detector inefficiency.

istered in the STS due to detector inefficiency. The resulting performance is presented in the table in Fig. 4.19. The overall reconstruction efficiency after the last iteration has improved by about 2%.

There is a special procedure implemented in the algorithm to suppress clones, which merges together potentially doubly reconstructed tracks. Also, there is a special extender option, which tries to extend tracks in both directions via search for unused hits, which can be attached to the already reconstructed track.

The reconstruction performance after switching on merger and extender options is presented in the table in Fig. 4.20. The clone level has decreased more than two times from 1.0% to 0.4% after switching the merger option on.

The majority of signal tracks (decay products of  $D$ -mesons, charmonium, light vector mesons) are particles with momentum higher than 1 GeV/ $c$  originating from region very close to the collision point. Their reconstruction efficiency is, therefore, similar to the efficiency of high-momentum primary tracks that is equal to 97.5%.

The high-momentum secondary particles, e.g. in decays of  $K_s^0$  and  $\Lambda$  particles and cascade decays of  $\Xi$  and  $\Omega$ , are created far from the primary vertex, therefore their reconstruction efficiency is lower — 91.1%.

Significant multiple scattering of low-momentum tracks in the material of the

**Figure 4.20:** Track reconstruction efficiency as a function of track momentum and track finder performance after merging clones.

detector system and large curvature of their trajectories lead to lower reconstruction efficiencies of 92.6% for primary tracks and of 63.8% for secondary low-momentum tracks.

The total efficiency for all tracks is 90.9% with a large fraction of low-momentum secondary tracks. The levels of clones and ghost tracks are 0.4% and 5.9% respectively.

The behavior of the CA track finder in the case of higher track multiplicity will be investigated in the next chapter.

# Chapter 5

## Track finding at high track multiplicities

### 5.1 Challenging track multiplicities in HEP

To validate the Standard Model, scientists aim to observe phenomena at ever higher energy densities and to measure their parameters with the highest possible precision. To achieve this one needs accelerators which are as powerful as possible and the most precise detectors. The multiplicity of some important rare probes is so low, that the statistically reliable measurement for them requires HEP experiments to operate at ever increasing collision rates. One can predict that in the future this tendency will only get stronger.

On the other hand, in the course of time, as one looks deeper into the structure of matter, particle detectors have been evolving from simple devices with a few channels to very complex multi-layer systems with several millions of read-out channels. Due to the ever increasing complexity of particle detectors and accelerators, the domain is a driving force for technology. The need to look for rare and complex signals forces the data acquisition systems and reconstruction algorithms to develop accordingly.

Fig. 5.1 shows the graph of the maximum trigger rates and event sizes for the operating experiments of the past three decades. The outermost points in this graph are clearly given by the four LHC experiments, with the general-purpose experiments (Compact Muon Solenoid (CMS) and A Toroidal LHC Apparatus

(ATLAS)) pushing both the rate and size frontier, and the two specialized LHC experiments pushing the rate (LHCb) and event size (ALICE) frontier, respectively. A data point for the future CBM experiment in the chart takes a place at  $10^7$  MHz and event size of 40 kB.

**Figure 5.1:** The graph of the operating requirements of some major operating experiments in high-energy physics in the past 30 years and some future experiments. The  $X$ -axis denotes the amount of data recorded in a single event, whereas the  $Y$ -axis represents the number of events per second that have to be read out and analysed by intelligent filters [101].

A new generation of experiments is now emerging, in which the track density is so high that success will crucially depend on the power of the reconstruction methods. For modern experiments the collision rates have reached such an extent that those are not only limiting the time available to perform reconstruction, but also forcing the experiment to face the pile-up challenge.

The pile-up is a situation when several events occur so close in time, that a particle detector has to process them simultaneously. For example, an event display of a pile-up of 25 events during ATLAS Run1 is shown in Fig. 5.2. For ATLAS Run2 the average pile-up is expected to increase by up to a factor of 2.5. The pile-up situation has a direct influence on the complexity of track

reconstruction procedure, since the track multiplicity in this case rises up by factors.

**Figure 5.2:** The event display of the ATLAS experiment illustrating the pile-up of 25 collisions. The reconstructed vertices are shown with different color [102].

For tracking it means more events with a more complex pattern to be looked at in less time. It results in stronger requirements to the speed and efficiency of the tracking algorithm. Naively one would expect the reconstruction complexity to scale with the number of tracks.

Unfortunately this is not the case, since the track finding is a combinatorial problem similar to the famous travelling salesman problem. It belongs to the class of NP-complete (nondeterministic polynomial time) problems according to the theory of computational complexity. Thus, it is possible that the worst-case running time for any algorithm for the problem increases superpolynomially (perhaps, exponentially) with the track multiplicity. Let us assume that a track finder is going to consider all possible combinations of  $N$  measurements in order to find the most probable set of tracks. Since the total number of combinations is  $N!$ , a full revision of all combinations is impossible for a large  $N$  within reasonable time.

Thus, the first challenge for track finding in the case of increased multiplicity is the exponential rise of the computing time per event — as suggested by combinatorics. Large detector occupancy leads to large combinatorics in track finding, making the algorithm much slower. Usually, faster algorithms are simply those that try “less combinations”.

Moreover, large track multiplicity leads to large detector occupancy and re-

sults in overlapping tracks. It naturally leads to increased number of wrongly reconstructed tracks. A robust tracking algorithm must be able to handle large variations in multiplicity. That is why the tracking stability becomes particularly important for the modern HEP experiments.

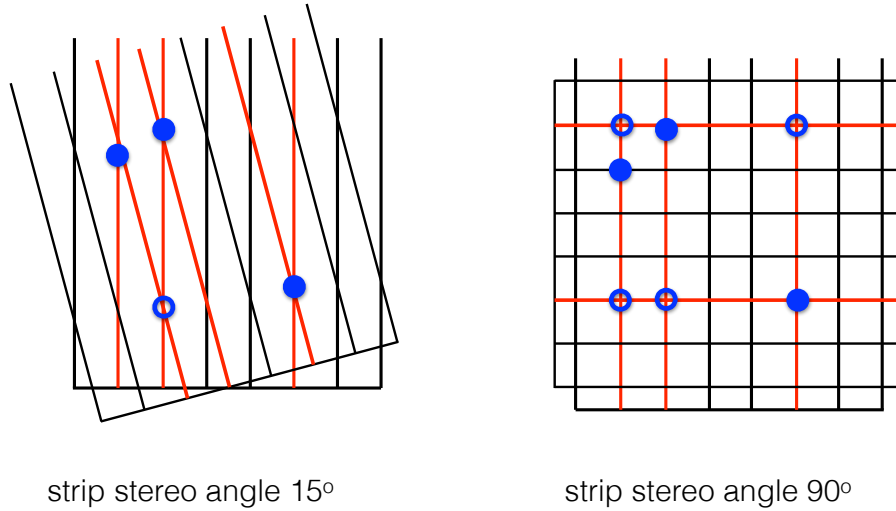

The simulations of the continuous CBM beam predict that the experiment also will have to deal with events overlapping in time. In order to test the CBM CA track finder behavior in the high track multiplicity environment, a special study was performed. The details of the study will be provided and discussed in the next section.

## 5.2 CA track finder performance at high track multiplicity

In order to test in a high track multiplicity environment the stability of the CA track finder algorithm described in the previous chapter a special study has been performed. A robust behavior of the algorithm in this test promises stability of tracking in the case of increased track multiplicity due to a pile-up or a beam instability.

However, the CBM experiment has some particular reasons to test tracking routines with respect to high track multiplicities. Since the CBM experiment will operate at extremely high interaction rates, different collisions may overlap in time, leaving no possibility to separate them in a trivial way. Thus, the need to analyze the so-called time-slices, which contain information from a number of collisions, rather than isolated events, arises.

The need to work with time-slices instead of events is driven not only by physical circumstances, but also is encouraged by computing hardware reasons. Not only minimum bias events, but even central events have been proven to be not big enough in order to be processed in parallel on a modern many core computer architectures. For implementing in-event level parallelism these events do not have enough sources of parallelism (like hits, segments, track candidates for different reconstruction stages) in order to be reconstructed on 20 or more CPU cores simultaneously.

**Figure 5.3:** The mechanism of generating fake hits (shown with empty circles) in a strip detector with strip stereo angle  $15^\circ$ : hit is identified as an intersection of active strips (shown in red), 3 real hits (shown with solid circles) generate 4 intersections (left side). A strip detector with strip stereo angle  $90^\circ$  due to higher stereo angle has even more fake hits (right side).

These reasons bring us to introducing the concept of time-slice to the reconstruction procedure. As a first step on a way towards the time-slice reconstruction we introduce a container of packed minimum bias events with no time information taken into account. To create such a group we combine space coordinates of hits from a number (from 1 up to 100) of Au+Au minimum bias events at 25 AGeV ignoring such information as event number or time measurements.

In order to obtain such quasi-time-slices a special script was written, which allowed packing the data from a number of minimum bias events into one super-event. Such super-event the standalone reconstruction package could take as input information the same way as a normal event [73, 103].

It is important to mention that this definition of a super-event does not precisely correspond to a pile-up simulation. The reason for this is that in this case fake hits in the STS detector are created from strips on the event level, not within the whole super-event.

It is a known fact that devices measuring single coordinates do not provide three-dimensional points on a trajectory, but rather projections. Such devices may be economic, since a relatively small number of channels is needed to cover

**Figure 5.4:** Reconstructed tracks in a minimum bias event (left) and in a packed group of 100 minimum bias events (right), 109 and 10 340 tracks on average respectively.

a region with a good resolution. However 3D information can be only obtained by combining several projections. Although 2 views are sufficient in order to reconstruct 3D space points, in the presence of multiple tracks this leads to ambiguities.

For this reason double-sided strip detectors, like STS, have a relatively large rate of reconstructed fake hits, which were not produced by any particle. The mechanism of fake hits production is explained in Fig. 5.3 and is due to the fact that a hit is defined as an intersection of simultaneously activated back and front strips. The number of such intersections does not correspond to the number of hits in general when several hits were produced simultaneously within the detector time precision.

The combined super-event was treated by the CA track finder as a regular event and the reconstruction procedure was performed with no changes (Fig. 5.4).

Varying the number of minimum bias events in a group from 1 to 100, the track reconstruction efficiency dependence has been studied with respect to the track multiplicity. The efficiency definition was the same as in the previous chapter. The resulting performance is summarized in Tab. 5.1. The comparison of performance results in cases of a normal minimum bias track multiplicity (column 3D mbias), central event (column 3D central) and the extreme track multiplicity of super-event made of 100 minimum bias events (column 3D + 1)

Efficiency, %	3D mbias	3D central	3+1 D
All tracks	88.5	88.3	80.4
Primary high- $p$	97.1	96.2	94.3
Primary low- $p$	90.4	90.7	76.2
Secondary high- $p$	81.2	81.4	65.1
Secondary low- $p$	51.1	50.6	34.9
Clone level	0.2	0.2	2.5
Ghost level	0.7	1.5	8.2
MC tracks found/event	130	622	118
Time/event	8.2 ms	57 ms	31.5 ms

**Table 5.1:** Track reconstruction performance for Au+Au collisions at 25 AGeV in the case of event-by-event analysis (3D) for minimum bias and central events, as well as for a hundred events grouped on a hit level with no time information (3 + 1D). No track merging and extending procedures are included.

is presented in the table.

As one can see in Fig. 5.5 high momentum primary tracks (High- $p$  Prim), which have particular physical importance, are reconstructed with excellent efficiency of about 96%, which varies within less than 2% for up to a hundred events grouped.

If we include secondary tracks (High- $p$  all) the efficiency is a bit lower — 93.7%, since secondary tracks may originate far from the target. This value varies within about 3% for the extreme case of 100 minimum bias events grouped. The efficiency for low momentum tracks is 79.8% (Low- $p$  all) in case of minimum bias track multiplicity and it changes within 6.5% window in case of the largest track multiplicities. The ghost fraction remains at acceptable level (not more than 10%) for up to the highest track multiplicities.

Thus, the CA track finder performance is proved to be stable with respect to the high track multiplicities.

A test of performance at a higher track multiplicities is possible in this case, but the efficiency definition needs to be modified. Since the hit density is so high and hit measurements lay so close to each other, taking a neighbor hit instead of a true hit does not affect reconstructed track parameters in the end. As discussed in section 4.2.5, in this case parameter matching efficiency definition may be more suitable.

**Figure 5.5:** Track reconstruction efficiencies, ghost and clone rates for different sets of tracks as a function of track multiplicity.

### 5.3 CA track finder speed vs. track multiplicity

However, not only an efficiency performance, but also the speed of a reconstruction algorithm is crucial for successful performance in the case of CBM. For the implementation of a track reconstruction application, the good behavior of the algorithm at high track multiplicities is essential, since e.g. an exponential rise of the computing time per event — as suggested by combinatorics — may tend to block computer nodes for an undue amount of time.

The time that the CA track finder needs to reconstruct a grouped event, was studied as a function of the number of Monte-Carlo tracks in a group (Fig. 5.6). The results show that the dependence is perfectly described with a second order polynomial. This is a promising result, if one keeps in mind the exponential growth of combinatorics with the track multiplicity.

In order to understand better the structure of the algorithm and how different parts of the algorithm cope with increased track multiplicity, let us consider how

**Figure 5.6:** The CA track finder time, needed to reconstruct groups of minimum bias events without time information, with respect to track multiplicity. The dependence is fitted with a second order polynomial.

the fraction of total time, needed for different parts of the algorithm, changes with respect to number of events in the group. The dependence is presented in Fig. 5.7.

As one can see for low track multiplicities triplet construction phase time is not as important, since the prevailing part here is initialization. The data amount in this case is small and, thus, can be loaded to cache memory. The triplet construction stage is fast in this case.

However, at high track multiplicities the situation changes, and triplet construction stage takes the major part of the algorithm time. Thus, one has to take particular care in optimizing this stage, since it tends to prevail in the case of increased combinatorics like no other stage. Since the major part of random hit combinations are rejected at triplet stage, the track construction stage is hardly affected by the increased combinatorics.

Summarizing, both speed and efficiency of CA track finder show stable behav-

**Figure 5.7:** The time fraction of different stages of the CA track finder algorithm as a function of a number of combined events. One can clearly see that the most sensitive towards combinatorics stage is the triplet construction.

ior at high track multiplicities.

The time dependence can be improved further and turn into a linear one, which corresponds to the case of event-based analysis, after introducing time measurements into the reconstruction algorithm. The next step for the algorithm development is to make its parallel implementation, which is the subject of the next chapter.

# Chapter 6

## Parallel CA track finder

One of the key ingredients for the successful operation of the CBM experiment is the development of fast and precise reconstruction algorithms suitable for online data processing. In order to benefit from the advantages of modern parallel computer architectures (many-core CPU/GPU), the existing reconstruction routines need to be redesigned with parallelism in mind. The desired efficient intrinsically parallel algorithms should reflect the massive hardware parallelism in computational scheme and data structures.

The CA track finder algorithm was redesigned and optimized with respect to parallelism. The algorithm demonstrates a linear scalability on a many-core CPU server, indicating the ability to be effectively run on a complex computer farm. While vectorisation allowed for processing in parallel data streams, many-core execution has enabled parallelism on the task level. The details of parallel CA track finder algorithm development as well as achieved performance are discussed in this chapter.

### 6.1 General overview of parallelisation strategy

Although intrinsic parallelism and data locality are the notable features of the CA track finder, still a lot of efforts were required in order to develop an efficient parallel implementation out of the existing vectorised, but sequential algorithm.

Reformulating the algorithm in terms of parallelism often may mean that it has to be drastically changed or even written from scratch, since an efficient

sequential version is not necessarily an efficient solution for a parallel run. Parallel implementation requires certain features for the algorithm. Firstly, in order to get correct results, the operations performed concurrently should be independent from each other. Secondly, one has to keep in mind that the parallel section should always be thread-safe, so that the shared data structures are used in a manner that guarantees safe simultaneous execution by multiple threads. This can be achieved by allocating local data structures to each thread and summarizing results of their work afterwards or, alternatively, introducing synchronization into thread execution.

The synchronization usually slows down the speed of a program, since threads have to wait for each other or exchange results of their work, so the use of this tool should be minimized. Also memory optimization and data structure scheme become essential in case of parallel programming, due to increased memory demand.

Thus, the CA track finder algorithm had to be redesigned with the idea of performant parallel processing in mind. The main goal at this stage was to create an entirely parallel implementation for a concurrent search for tracks within a single grouped super-event (quasi time-slice). The target implementation should show the maximum achievable speed-up factor on the testing architecture, while still being fast in sequential run and providing stable and reliable results. Although this issue is closely connected with the algorithm speed, particular attention was devoted to the data structures and memory optimization.

The vectorized, but sequential in terms of core usage, version of the CA track finder was taken as the starting point for developing a parallel version with the use of the OpenMP and Pthreads interfaces.

Here it is important to highlight the difference between embarrassingly parallel reconstruction of independent events concurrently, which is to a certain extent trivial, and the problem of distributing a bunch of dependent tasks, performed while reconstructing tracks produced in a time-slice in a parallel run. Unlike the case of different events, where no synchronization by default is needed, the reconstruction of a time-slice in parallel requires synchronization, so that the work is distributed between threads in an efficient and thread-safe manner with no race conditions.

**Figure 6.1:** The parallelisation strategy and the data flow of the parallel CA track finder algorithm. All stages of the algorithm can be executed in parallel using a number of cores. The synchronization between threads is minimized: it is only needed during initial hit sorting and track selection stages.

Since the major part of the tracks in CBM are straight, the logical extension of the approach of event level parallelism would be to cut virtually the detector into areas and reconstruct tracks in parallel inside those areas. However, this strategy was not approved, since it makes the method less general and is binding to a certain detector and physics case. Also, the search for low-momentum curved tracks becomes difficult in this case.

Instead, each step of the CA track finder algorithm was examined in order to reveal potential sources of parallelism. Fig. 6.1 depicts the overview of processing steps of the developed parallel CA track finder implementation. At each stage the source of parallelism elements are concurrently processed and stored in a new form with a higher consolidation extent.

During the initialisation stage all the input hits are sorted and stored according to the grid structure. Also, all the hits are split into portions with a number of hits, divisible by the SIMD-vector width, for the future vectorized processing.

At the triplet building stage portions of hits are processed concurrently with no synchronization between threads giving as a result a set of triplets.

At the next stage of track candidate construction triplets are the source of parallelism. For each starting triplet the algorithm creates concurrently the best possible track candidate according to  $\chi^2$ -value and length. At this point threads are still working independently, unlike the last stage of track selection, where threads have to consult each other in order to divide the hits between the reconstructed tracks. At the track selection stage the synchronization was implemented via a table of common access.

At the final stage the hits, used in the accepted reconstructed tracks, are removed from the input for the next iteration. Similar to the initialization stage, at this point the hits represent the source of parallelism.

As far as the number of parallelism source elements is concerned, it is obvious that its amount is growing linearly with the number of events in the input. Hence, this amount can be controlled and in future the time length of a time-slice can be chosen proportionally to a compute power of the processing node in order to fully utilize hardware resources. In order to have enough sources of parallelism to fill the whole CPU a super-event of 100 minimum bias Au+Au events was chosen for the study and optimization .

An important issue while making a parallel implementation is to keep in mind a certain computer architecture. The optimization and testing of the parallel CA track finder was performed on the lxir075 server at GSI, which is equipped with four Intel Xeon E7-4860 processors. It can operate in total with 80 threads in parallel (Fig. 6.2). Each processor has 10 physical cores with hyper-threading. It is an example of the NUMA architecture, that means that the memory access time for the server depends on the memory location relative to the processor. CPUs can communicate and exchange data between each other, but it takes longer than accessing local CPU memory. Thus, the decision was made to send one super-event to a single CPU for reconstruction, not to the whole node, in order to avoid processors communication. This way such an architecture can be filled with 4 super-events reconstructed in parallel.

The Intel Xeon E7-4860 is a server processor that was first available for purchase in April 2011. It operates at a stock clock speed of 2.26 GHz. Following

**Figure 6.2:** The lxir075 server at GSI is equipped with four Intel Xeon E7-4860 processors. Due to HTT, it can operate in total with 80 threads in parallel.

the NUMA concept 16 GB of RAM is attached to each CPU. QPI allows CPUs to access remote memory of each other. As for the cache memory, each core of the Intel Xeon E7-4860 CPU has 32 KB of L1 cache for instructions, 32 KB of L1 cache for data and 256 KB of L2 cache for data and instructions. In addition, each CPU contains 24 MB of L3 cache memory, which is shared among the cores.

If one keeps in mind that vector registers contain up to 4 float or integer data elements in case of SSE instructions, the total pure hardware potential speed-up factor of the lxir075 server can be calculated as follows:  $f = 4 \text{ sockets} \cdot 10 \text{ cores} \cdot 1.3 \text{ threads} \cdot 4 \text{ SIMD} \approx 200$ . If we ex-

clude vectorisation, the potential speed-up factor due to multithreading alone within one CPU is:  $f = 10 \text{ cores} \cdot 1.3 \text{ threads} \approx 13$ .

Algorithm step	% of total time
Initialization	2.0
Triplets construction	90.4
Tracks construction	4.1
Final stage	3.4

**Table 6.1:** The fraction of the total execution time for different steps of the CA track finder algorithm in a sequential run.

Let us briefly go through each step of the CA Track Finder algorithm, outlining which source of parallelism was used at each stage and what kind of changes were made in order to reconstruct tracks in parallel inside one grouped event. The list of the stages as well as the fraction of the total execution time for each of them can be found in Tab. 6.1.

## 6.2 Initialization and final stages

The initial stage, when the input information for the algorithm gets prepared, can be split into two logical parts:

- memory allocation for the input information,
- ordering the input information in the suitable for the track finder format: sort hits according to the grid structure and split them into portions.

### Memory allocation

In the original serial version of the algorithm, the memory was reallocated for each event again in the very beginning of the CA track finder. No doubt, this approach has an advantage, since in this case the algorithm knows in advance how much memory is needed to store input and can allocate exactly the amount of memory needed.

However, this way double work is done, since the memory originally allocated for a certain event is released at the end of event reconstruction and has to be

allocated again at the initial stage of the next event reconstruction. In case of a single minimum bias event reconstruction this allocation time is negligible, but in case of time-slice reconstruction it becomes significant.

One more obstacle of this approach is that memory allocation represents an essentially sequential process and, thus, cannot be efficiently performed in parallel. Keeping in mind these aspects, the decision was made to reuse the memory, once allocated for the first reconstructed event. The memory should be allocated once before calling the track finder routine for a grouped super-event (or, in future, time-slice). For further reconstruction the memory volume, if needed, should be extended.

Unfortunately, one cannot know in advance the size of input information. It varies from one time-slice to another. For instance, it is possible that the next reconstructed time-slice contains more hits and, thus, more memory is required to store input information. Partial solution would be to estimate the average size of time-slice and allocate an excessive amount of memory. But this does not guaranty a safe execution, in case of some irregular situations. In order to overcome this obstacle a special class, named `L1Vector`, was introduced for a safe execution in case of unpredictable increase in the volume of input information.

The `L1Vector` class declaration is presented in List. 6.1. This class is based on the standard library vector class, but has some extra functionality. The `L1Vector` has a private member – `fSize` — to store the number of meaningful elements, in addition to the normal `std::size()` — which corresponds to the actual size of the vector array. If a new element is stored to the array, `fSize` is increased by one, but the actual size of the array gets increased only if `fSize` gets larger than `std::size()` (lines 8–11). Certainly, one should avoid situations when two independent threads are trying to change the size of an array. For this reason these lines are executed under `#pragma omp critical` directive to force sequential execution at this point.

Before calling the track finder routine, the algorithm resizes all the input vectors to the estimated size of time-slice input information. In the reconstruction routine the algorithm tries to store input information in the already allocated arrays, but each time checks if allocated memory is enough to do so. If not, it will allocate additional memory. This approach avoids double work, while

working fast in normal case, when there is enough memory. Also it guaranties a safe execution in the case of unexpected memory excess.

```

1 #include <vector>
2 template <typename T> class L1Vector: public std::vector<T>
3 {public:
4 // return number of meaningful elements
5  unsigned int  Size() const { return fSize; } /* set number of
6  meaningful elements to zero */
7  void Resize(const unsigned int n) { /* resize only to a larger
8  size */
9      if(n > std::vector<T>::size()) {
10         #pragma omp critical
11         std::vector<T>::resize(n);
12     }
13     fSize = n;
14 }
15 T& operator[] (const size_t index) { /* if no element exists --
16 create one */
17     if(index >= std::vector<T>::size()) {
18         #pragma omp critical
19         std::vector<T>::resize(index+1);
20     }
21     if(index>=fSize)
22         fSize = index + 1;
23     return std::vector<T>::operator[] (index);
24 }
25 private: unsigned int fSize;
26 };

```

**Listing 6.1:** A class to store algorithm input information. Provides a safe way to reuse the previously allocated memory for the time-slice reconstruction.

Thus the operation of memory allocation, which took place in the original version of the algorithm, was avoided in the execution scheme of the parallel

track finder.

### Grid structure

The importance of fast access towards hit measurements in a certain spacial area of a station for the CA track finder algorithm cannot be overestimated, since it plays the central role at the time-consuming stage of triplet building. The role of memory access in case of parallel calculations becomes even more important, since the data flow increases proportionally to the number of threads accessing the memory.

In order to avoid random memory access and benefit from cache line reading approach, a regular 2D grid data structure was used on each station in the original event-based algorithm scheme. The memory optimization in this case allows fitting all calculations to smaller and faster caches.

Every measurement belongs to some bin in the structure according to its spacial  $x$  and  $y$ -coordinates. All hits are sorted and saved in the order of their bin number and for each bin the index of first hit in this bin is stored.

Thus, the procedure of introducing a grid structure can be divided into several logical steps:

- define the size of bins according to the hit density,
- order the hits according to the bin number,
- count the number of hits in each bin,
- store the index of the first hit in the bin for each bin.

In the original version of the CA track finder for the grid sorting procedure the standard C++ library `std::sort` function was used, which corresponds to quicksort algorithm with an  $O(N \log_2 N)$  complexity. However, the quick sort algorithm is not an optimal solution in this case. For example, since all possible values of the bin number are known, one can apply the counting sort algorithm here.

The counting sort is a very efficient, in-place, high-performance sorting algorithm. For arrays of numbers it does not move the elements, but instead counts the occurrence of each possible value, and constructs the sorted array from these

**Figure 6.3:** An Illustration of the Up-Sweep phase of a work-efficient prefix sum algorithm.

**Figure 6.4:** An Illustration of the Down-Sweep phase of a work-efficient prefix sum algorithm.

counts. Counting sort determines, for each input element  $x$ , the number of elements less than  $x$ . It uses this information to place element  $x$  directly into its position in the output array. Counting sort is a linear-time  $O(N)$  algorithm, which performs  $2n$  amount of work —  $n$  for reading/counting,  $n$  for writing/constructing. In addition to that, the counting sort algorithm is more suited for a parallel implementation.

The counting sort scheme for the grid structure was implemented as follows: having calculated the bin size according to the hit density, the algorithm loops over all hits, defining for each hit a bin number, and calculating how many hits are in each bin. In order to obtain the first hit index in each bin the algorithm calculates prefix sum on the array with the number of hits in each bin. In the next loop over hits each hit is placed to a proper place in a sorted output array according to the corresponding bin number.

Most of the procedures in this scheme are trivial to run in parallel. However, the essential part of the scheme is the calculation of exclusive prefix sum (also called exclusive scan). Thus, the task of parallelisation of this part is reduced to the task of parallel implementation of exclusive prefix sum algorithm.

Since prefix sum is a useful building block for many parallel algorithms, including sorting and building data structures, it has been implemented for many parallel systems. The work-efficient parallel prefix scan algorithm has been proposed by Blelloch [104] and optimized with a divide-and-conquer strategy. The proposed

solution was to make a use of balanced binary trees, which often arise in parallel computing. The procedure is performed in place and consists of two phases: the *up-sweep phase* and the *down-sweep phase*. The *up-sweep phase* (Fig. 6.3) traverse tree from leaves to root, computing partial sums on the way. The *down-sweep phase* (Fig. 6.4) traverse the binary tree back from root to leaves, using the partial sums to compute the prefix sums in place.

---

**Algorithm 1** Up-Sweep Phase
 

---

```

1: for  $d \leftarrow 0$  to  $\log_2(n) - 1$  do
2:   for all  $i \leftarrow 0$  to  $n - 1$  by  $2^{d+1}$  in parallel do
3:      $a[i + 2^{d+1} - 1] \leftarrow a[i + 2^d - 1] \oplus a[i + 2^{d+1} - 1]$ 
4:   end for
5: end for

```

---

---

**Algorithm 2** Down-Sweep Phase
 

---

```

1: for  $d \leftarrow \log_2(n) - 1$  downto  $0$  do
2:   for all  $i \leftarrow 0$  to  $n - 1$  by  $2^{d+1}$  in parallel do
3:      $a[i + 2^{d+1} - 1] \leftarrow a[i + 2^d - 1] \oplus a[i + 2^{d+1} - 1]$ 
4:   end for
5: end for

```

---

The *up-sweep* and the *down-sweep* phases have  $\log(n)$  steps and the complexity of  $O(n)$ . Therefore the complete algorithm has the total complexity of  $O(n)$  and needs  $2 \log n$  steps to compute the prefix-operation on the given array.

The parallel OpenMP implementation for the complete algorithm is given in Listing 6.2. The `parallel pragma` defines a start of a parallel block. At this point a set of  $N$  threads, where  $N$  is given at the runtime, are created, all of which execute the next parallel block. The `for` directive splits the following for-loop so that each thread in the current parallel block gets a portion of the loop iterations for the execution. The scheduling clauses for the for-loop define the way, how the iterations are distributed between threads. In the algorithm, the dynamic scheduling was chosen to process the for-loop concurrently. In this case

each thread grabs a chunk of iterations from a queue, as soon as it has finished the previous work, until all iterations have been handled.

```

1  int j = 2;
2  /* Up-Sweep Phase */
3  for (int i = 1; i < N_values; i = j) {
4      j = i << 1;
5      #pragma omp parallel for schedule(dynamic)
6      for (int m = j - 1; m < N_values; m += j) {
7          array[m] = array[m - i]+array[m];
8      }
9  }
10 /* Down-Sweep Phase */
11 for (int i = j >> 1; i > 1; k = j) { j = i >> 1;
12     #pragma omp parallel for schedule(dynamic)
13     for (int m = i - 1; m < N_values - j; m += i) {
14         array[m + j] = array[m]+array[m + j];
15     }
16 }
17

```

**Listing 6.2:** The parallel implementation of prefix scan algorithm with OpenMP.

Similar to the initial stage in the final stage the algorithm processes hits in parallel and removes used hits from consideration for the next stages. In addition to this, the grid structure needs to be updated accordingly.

### 6.3 Triplet building stage

The triplets, constructed out of hits in the adjacent detector layers, are the basic building blocks for the further track construction. The triplet building stage is the most time consuming as well as the central stage of the algorithm. The result of the previous stage, the grid hit structure, is extensively used at this stage, providing fast access to the hit measurements in a certain spacial area of a station. The main parallelization idea at this stage is to process in parallel

groups of starting hits, formed during the initialization stage.

This stage of the CA track finder algorithm is intrinsically parallel and works locally with respect to the data. Due to this fact, there was no need to drastically redesign this part. However, several crucial optimizations had to be done in order to reveal the parallelism, which was hidden by the technical issues.

One particular example of inappropriate memory usage for a parallel run is the way triplets were stored in the memory in the original algorithm version. The constructed triplet was saved by allocating memory for each new object again and afterwards storing this object to the array of triplets, by calling the `push_back()` function of the standard library C++ vector:

```
1 L1Triplet triplet;  
2 triplet.Set( ihitl, ihitm, ihitr, istal, istam, istar,  
3             0, qp, chi2); /* Set triplet parameters */  
4 vTriplets.push_back(triplet); /* Store the triplet to array */  
5
```

**Listing 6.3:** The sequential implementation of storing the constructed triplets.

While it is a correct and efficient procedure in the case of sequential run, in a parallel implementation this piece will work neither correctly, nor efficiently.

The first reason for the wrong results is that several threads possibly try to store triplets to the same array at once. Parallel implementation requires so-called thread-safe execution, which means that for each thread one needs to provide a separate array to store the data in order to avoid conflicting threads.

```
1 L1Triplet & tr = TripletsLocal[omp_get_thread_num][triplet_num++];  
2 tr.Set( ihitl, ihitm, ihitr,  
3        istal, istam, istar,  
4        0, qp, chi2); /* Set triplet parameters */  
5
```

**Listing 6.4:** The parallel implementation of storing the constructed triplets.

The second reason for an inefficient parallel execution of the example is that in this case the array of triplets will grow gradually and at some point there will not be enough space to store all the array elements in the initial location. In

this case the CPU will have to move the whole array to a new memory location. This time-consuming procedure will happen many times throughout the program execution and will ruin the algorithm potential for parallelism.

In order to solve this issue, the memory for the constructed triplets must be allocated in advance, similar to the way as it was done for the input hit information. The proposed solution is shown in List. 6.4. This way the CPU does not have to repeatedly perform the data relocation, since from the beginning it has enough memory to save all the triplets to be built during the algorithm execution. This issue was solved for several arrays used to store the output information during the triplet building stage.

One more optimization was introduced to the triplet building stage in order to reduce the number of memory accesses. In the initial event-based track finder version, there was a special function, which was performing the task of finding and storing the neighboring relations between the constructed triplets. This procedure was done in a loop over the array of triplets, after all of them had been built. Since the triplets are built in a loop over starting hit stations, one can notice that at the point, when the algorithm builds triplet on a certain station  $N$ , its potential neighboring triplets, which should start on the station  $(N - 1)$  have already been built. Thus, all the information needed in order to define the neighboring relations between triplets is available at the point the algorithm accepts a certain triplet. The idea was to shift this task into the triplet building stage, so that it is done on the fly in the triplet building loop. This way we get rid of additional loop over all constructed triplets.

According to the definition neighboring triplets are those ones that share two hits in common and coincide within certain errors in the momentum. The following scheme was chosen in order to implement the search for neighbors on the fly while building triplets. A special array with the size of hits was introduced (List. 6.5). The link to each approved triplet is stored in the array according to its starting hit. Having this structure, the only thing one needs to do in order to obtain all the neighbors for a certain triplet  $T$  is to take the triplets starting with the middle hit of  $T$  and check whether their next hit also coincides with the hit of the supposed triplet. Also the momenta of both triplets should coincide with each other within estimated errors.

```

1  L1Triplet & T=TripletsLocal[omp_get_thread_num][triplet_num++];
2  TripletsStartWithHit[T.GetLHit()].push_back(&T); /* Store the
   link to the triplet for a corresponding starting hit */
3
4  for ( int i=0; i < TripletsStartWithHit[T.GetMHit()].size(); ++i
   ){
5
6     L1Triplet* &Neighbour = TripletsStartWithHit[T.GetMHit()][i];
7     const fscal &qp2 = Neighbour->GetQp();
8     fscal &Cqp2 = Neighbour->Cqp;
9
10    if (Neighbour->GetMHit() != T.GetRHit()) continue; /*
   Check for the 2nd common hit */
11    if ( fabs(T.qp - qp2) > (T.Cqp + Cqp2) ) continue; /* Check
   for momenta to coincide within errors */
12    T.neighbours.push_back(Neighbour);
13 }
14

```

**Listing 6.5:** The implementation of defining neighboring triplets on the fly.

With the above-mentioned modifications the triplet building stage can be run in parallel by a number of independent threads with no synchronization needed. As an output each thread provides an array of constructed triplets together with their neighboring relations.

## 6.4 Track construction stage

Having constructed triplets, the algorithm should combine them into tracks. As a result the algorithm has to provide a set of the longest tracks, which have the minimal  $\chi^2$ -value and share no hits in common. This stage can be arbitrarily divided into two logical phases. During the first phase for each possible starting triplet algorithm builds all chains of possible neighbors and out of this tree of

candidate chooses and stores the best one according to the  $\chi^2$  and the length. During the second phase the track competition takes place, when each survived candidate gets stored only if it shares no hits in common with a better candidate according to the  $\chi^2$  and the length.

### Track candidate formation stage

Let us consider the first phase of joining compatible segments into a track candidate (Algorithm 3). During the track candidate formation stage the algorithm tries to join segments into track candidates, starting with the outermost layer proceeding inwards towards the beam line. Since the level of each triplet had been obtained at the stage of building triplets, the procedure of binning triplets together can be performed in a fast and easy manner.

The final goal is to obtain the best set of tracks according to  $\chi^2$ -value and track length. Therefore, the algorithm starts building tracks out of triplets with the highest calculated level, since these triplets have a higher probability to construct the longer tracks. The algorithm starts the track building procedure with an attempt to build longer tracks at first and in a loop decreases the potential length of the track candidate being built down to the tracks of three or four hits (line 1, length is calculated in the number of connected triplets building up the track).

During the search for the candidate of a certain length the algorithm must consider as a starting triplet all triplets on each station, from which it is still possible to build up a candidate with the length of interest (lines 2–3). Each triplet considered as a starting triplet has to fulfill two conditions:

- should be potentially able to create a track of a certain length (line 4),
- has no hits used in the longer tracks constructed before.

For the triplet, which fulfills both conditions, a special recursive function is called. The function creates a tree of track candidates and chooses the best track within this tree.

The function (Algorithm 4) takes as input three arguments: the starting triplet itself, the track candidate containing the left hit of the starting triplet (created in

---

**Algorithm 3** For each starting triplet build and store the best track candidate.

---

```

1: for each track  $length \leftarrow (NStations - 3)$  downto  $minLevel=(1 \text{ or } 2)$  do
2:   for each starting  $Station \leftarrow 0$  to  $(NStations - 3 - length)$  do
3:     for all triplets on station do
4:       if ( $Triplet.Level < length$ ) continue;
5:       if ( $Triplet.LeftHitIsUsed$ ) continue;
6:       create  $L1Branch$  candidate  $Cand$  with left hit of  $Triplet$ ;
7:        $L1Branch \text{ BestCand} = Cand$ ;
8:       ExtendCandidate( $BestCand, Cand, Triplet$ );
9:       if  $BestCand.Length < (length+1)$  continue;
10:      if  $BestCand.Length < (minLevel + 3)$  continue;
11:       $vTrackCandidates.Store(BestCand)$ ;
12:    end for
13:  end for
14: end for

```

---

the line 6, Algorithm 3) and the track candidate called `BestCandidate`, which for the initial call coincides with the candidate (created in the line 7, Algorithm 3).

Inside the function body the algorithm checks whether the considered triplet is the last triplet of the track ( $Level = 0$ ) (line 2, Algorithm 4). If so, the middle and last hits of the triplet are checked not to be used and added to the `BestCandidate`.

If the triplet is not the last one in the chain and has neighbors (line 8, Algorithm 4), then the algorithm goes through the list of its neighbors and tries to attach each neighbor to the existing chain. On each attempt the  $\chi^2$ -value is checked not to exceed the certain value (line 14, Algorithm 4). If this condition is fulfilled the function calls itself with the updated `BestCandidate`.

Thus, in a recursive manner the tree of all possible candidates, which start with the current triplet, is created and the best one is chosen. At this point function `ExtendedCandidate` terminates and returns the best track candidate built for a certain starting triplet. The length of this candidate is checked that it is not shorter than the required value, so that the candidate should not lose more than one hit (line 10, Algorithm 3).

---

**Algorithm 4** Recursive function to add next triplet to the track candidate.

---

```

1: procedure EXTENDCANDIDATE(BestCand, NewCand, Neibouhr)
2:   if Triplet.Level = 0 then
3:     if (! Triplet.MiddleHitIsUsed) add hit to Cand;
4:     if (! Triplet.RightHitIsUsed) add hit to Cand;
5:     if (Cand.Chi2 > Chi2Cut) return;
6:     else BestCand=Cand return;
7:   end if
8:   if !Triplet.Level = 0 then
9:     for each Triplet.Neibouhr do
10:      if Triplet.Neibouhr.LeftHitIsUsed then BestCand = Cand;
11:      else
12:        L1Branch NewCand = Cand;
13:        add left hit of Triplet to NewCand;
14:        if (NewCand.Chi2 > Chi2Cut) continue;
15:        ExtendCandidate(BestCand, NewCand, Neibouhr);
16:      end if
17:    end for
18:  end if
19:  return;
20: end procedure

```

---

Since each starting triplet is processed independently at this point, introducing the parallelism at this stage is trivial: each thread should process a set of starting triplets and create the best track candidate for each triplet in the set. No synchronization is needed at this point. So similar to the triplet building stage, the main performance issue here is the memory usage. The procedure of saving the accepted track candidate has been changed accordingly.

### Track competition

After all track candidates of a certain length have been constructed, the track competition takes place. In the end of this procedure each hit should participate

in not more than one track. This procedure is aimed at ghost suppression, since each hit is always attached to the best possible track according to the length and the  $\chi^2$ , which has a higher probability of being produced by a real particle.

This stage of the algorithm had to be essentially rewritten for the parallel implementation, since the scheme used in the event-based reconstruction was intrinsically serial. Originally the following scheme was used: all the tracks were sorted according to their length and  $\chi^2$ -value. The best track of all the tracks built at this stage was considered and checked to have any used hits. If the track had no used hits it was saved. In the case of presence of used hits it was discarded. The same procedure was done with each track in the order of their quality rank.

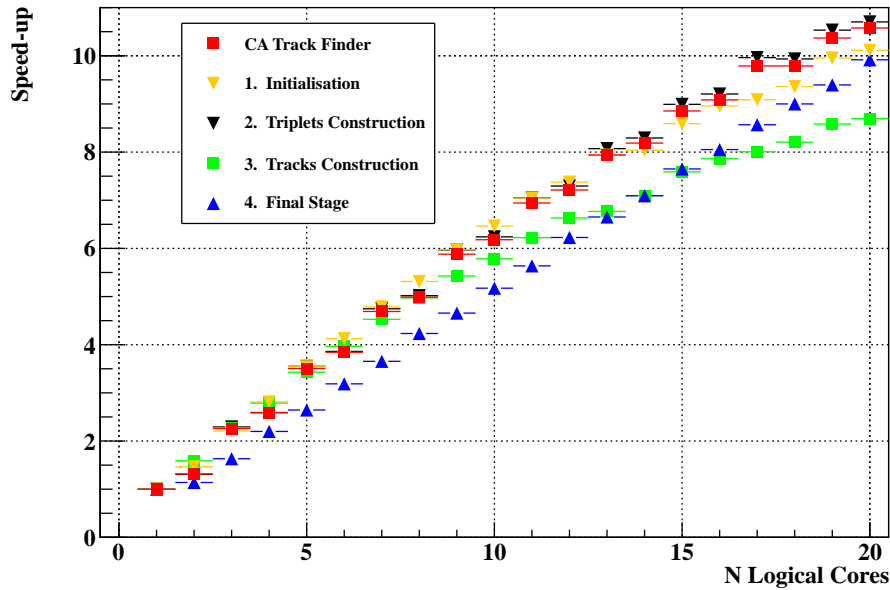

If a track candidate gets discarded due to the presence of a used hit, it will be constructed again in the next iteration during the search for a shorter candidate with one hit less.

Thus, unlike the triplet building stage, at this point we cannot avoid synchronization between threads, since in this case threads have to consult each other in order to decide to which track-candidate a certain hit should be attached in order to obtain the best set of tracks in the end.

It is clear that this part of the algorithm was essentially serial, since each next iteration essentially depends on the result of the previous iterations. Therefore, this stage of the algorithm had to be designed from scratch in a parallel manner.

The alternative approach, which allows for a parallel run, was proposed. The information exchange between threads was implemented via the table of common access available to all the threads. The size of table corresponds to the number of strips, contributing to the current super-event. For each strip in the table the index of the best, according to  $\chi^2$ -value and length, candidate is stored. The table is filled out on the fly while building track candidates. At the end of this procedure for each strip in the table the index of the best candidate is stored, which the strip should be assigned to.

Thus, the track competition reduces to the checking whether a certain track candidate is the best candidate for all the strips, which it involves. This check can be done concurrently for different track candidates with no synchronization needed.

**Figure 6.5:** The speed-up factor due to parallelisation for different steps and the full algorithm on the Intel Xeon E7-4860 CPU with 10 physical cores and the Intel hyper-threading technology for the case of reconstruction of 100 minimum bias Au+Au events at 25 AGeV grouped. The achieved speed-up factor for the full CA track finder reconstruction algorithm is 10.6.

## 6.5 CA track finder scalability on Intel Xeon E7-4860 CPU

The resulting scalability and the speed-up factors for different steps as well as for the full algorithm, obtained within one Intel Xeon E7-4860 CPU (20 hyper-threaded cores), is presented in Fig. 6.5.

As it was mentioned earlier, the algorithm consists of several logical parts. First, a short (2% of the total execution time) initialization, used to prepare hit information for tracking, takes place. The main and the most time-consuming part of triplet construction takes about 90% of the sequential execution time. Out of triplets the tracks are constructed, that takes about 4%, and in addition 3.4% for a final stage, when the input information for the next iteration is prepared.

All steps of the algorithm were parallelized inside the event, using different sources of parallelism in each step: hits in the initialization and final stages,

triplets for the major part, track candidates for the track construction step.

Some steps have a better speedup for higher number of cores due to less thread synchronization needed. The algorithm shows linear scalability. Due to the hyper-threading one can expect a speed-up factor of about 13 on such a CPU in the ideal case. The achieved speed-up factor is 10.6 for the full CA track finder reconstruction algorithm on a CPU with 10 physical cores with the Intel hyper-threading technology.

# Chapter 7

## Four-dimensional parallel track finder algorithm

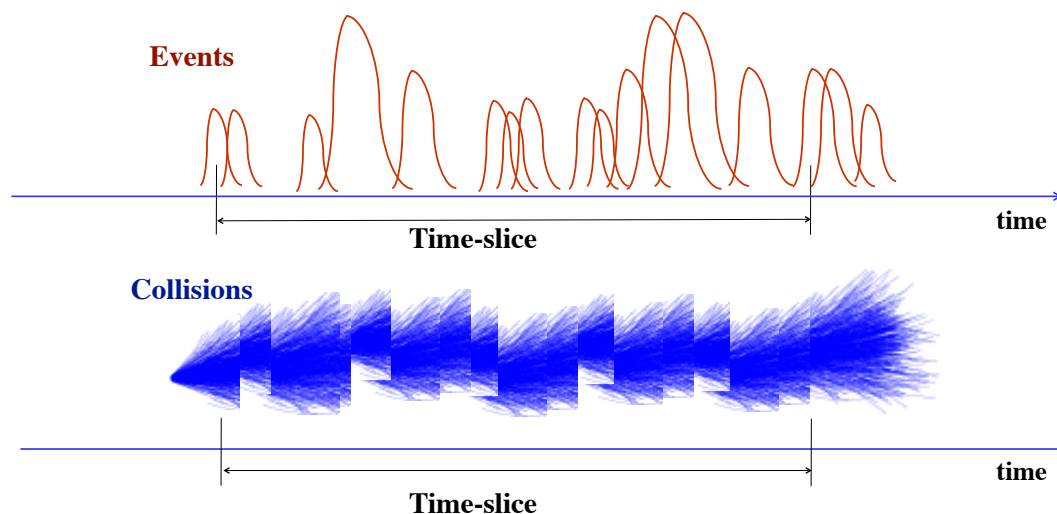

The unprecedented interaction rates for a heavy-ion collision experiment in CBM require a novel read-out and data acquisition concepts.

At the collision rate of 10 MHz, the expected raw data flow is about 1 TB/s. This is beyond the modern achievable archival rate, which means that the data flow has to be reduced online by about two orders of magnitude. However, since CBM is targeted to the measurement of rare observables, which are featured with a complicated trigger signatures, the experiment requires a full event topology reconstruction to be done online.

The huge data rates together with the absence of simple hardware triggers make traditional latency-limited trigger architectures typical for conventional experiments with a hardware trigger inapplicable for the case of CBM. Instead, CBM will employ a novel data acquisition concept with autonomous, self-triggered front-end electronics.

The time-stamped data will be shipped and collected into a readout buffer in a form of a time-slice of a certain length, which will be adjusted to the computational power of the reconstruction node. The time-stamped data will be delivered to a large computer farm FLES.

This novel concept brings new challenges for software developers. CBM will have to deal with a fraction of collisions, which overlap in time and can not be resolved in a trivial way (Fig. 7.1). Thus, the task of defining physical events is

**Figure 7.1:** The illustration of the complexity of defining physical events in the case of the CBM experiment: the absence of a hardware trigger together with extreme collision rates lead to a fraction of collisions, which overlap in time. Thus, the task of event building is shifted from the hardware to the software.

shifted from the hardware to the software designers.

If in conventional experiments with event-by-event processing the association of detector hits with a corresponding physical event was known *a priori*, it is not true for the CBM, where the reconstruction algorithms should be modified in order to process non-event-associated data. In this case the association of the hit information with physical events must be performed in software and requires full online event reconstruction not only in space, but also in time, so-called 4-dimensional track reconstruction.

In order to study the problem of event association and to develop proper algorithms, simulations must be performed which go beyond the traditional event-by-event processing as available from most experimental simulation frameworks.

The current chapter is devoted to the challenges of the free-streaming data reconstruction, the detailed description of the 4D tracking algorithm and the first version of the event building procedure, based on the developed tracking algorithm.

## 7.1 Time-slice concept

The CA track finder was proved to work quickly and reliably with respect to the track multiplicity. Moreover, the algorithm parallel implementation shows a strong linear scalability on many-core architectures. This implementation was used to develop the time-based algorithm.

One particular problem, often addressed while discussing the time-slice-based reconstruction, is the problem of possible event splitting on the border of two consecutive time-slices. Indeed, as it is seen in Fig. 7.1, if one just cuts the data into time-slices of a certain length, the information of a certain border collision may be split in two parts included in two different time-slices. Although this effect is negligible, since the length of time-slice is significant, the attempt to reconstruct such time-slices, ignoring the presence of such events, may lead to the loss of data.

One way to avoid such situations is to introduce a border time region of a certain length, which will be duplicated and present in both time-slices. This duplicated region will be examined and a time point with no data will be found. A deterministic algorithm will re-define time-slices at this point by sending the data before this point to the first time-slice, after this point — to the consecutive time-slice. This procedure guarantees the correctness of reconstruction, while avoiding duplicated work.

The next step towards the time-slice-based reconstruction is to take into account the time measurements of the STS detector in the tracking procedure. The beam at FAIR will correspond to a free stream of particles without a bunch structure. Thus, the feasibility studies must be performed time-slice-wise, since the traditional event-by-event analysis cannot reproduce the real life case for CBM. In order to switch to the time-slice-based analysis, at first one needs to obtain a simulation of a time-slice.

A dedicated procedure was introduced in order to group the Monte-Carlo hits delivered by the event-by-event transport code into time-slices. At first, a group of 100 Au+Au minimum bias events at 25 AGeV was taken. In future the number of events in a time-slice can be changed easily and should be adjusted to the power of the processing computing node.

**Figure 7.2:** The distribution of the hit time measurements for 100 minimum bias Au+Au collisions at 25 AGeV in the main tracking system of CBM, obtained assuming the average interaction rate of 10 MHz and Poisson distribution of the time intervals between subsequent events (top), the same distribution shown on a larger scale (bottom). Different collisions are shown with a different filling and color. Events clearly overlap with each other.

Neglecting possible fluctuations in the beam intensity and, thus, non-constant average collision rate, the CBM collision distribution in time can be described as a Poisson process. The start time of each collision was obtained with the Poisson distribution, assuming the average interaction rate of  $10^7$  Hz. A time stamp, assigned to each STS hit was calculated as a sum of the start time of the event, in which it was produced, and the time shift due to the time of flight from the collision point to a hit position. On top of that to obtain a time measurement for a hit in STS, the time stamp was smeared according to the Gaussian distribution with a  $\sigma$ -value of the STS time measurement resolution — 5 ns.

As a direct outcome of this procedure, the distribution of hit time measurements in the STS detector for a time-slice of 100 mbias events at 10 MHz interaction rate is presented in Fig. 7.2. The distribution clearly shows that at this interaction rate events do overlap with each other. Thus, the association of hits with events is no longer trivial.

Therefore, event reconstruction must be performed not only in space, but also in time. Space-time correlations must be employed, so that the tracking procedure takes into account not just three spacial dimensions, but the fourth dimension — time.

## 7.2 Time-based track reconstruction

As a first step towards development of the time-based tracking, the software reconstruction routine was extended to deal with time-based data instead of isolated events. After the algorithm was modified to be able to take time-slices as an input, the procedure of searching for tracks should be changed accordingly, so that the time information is used in order to improve the performance and the speed of the track finder.

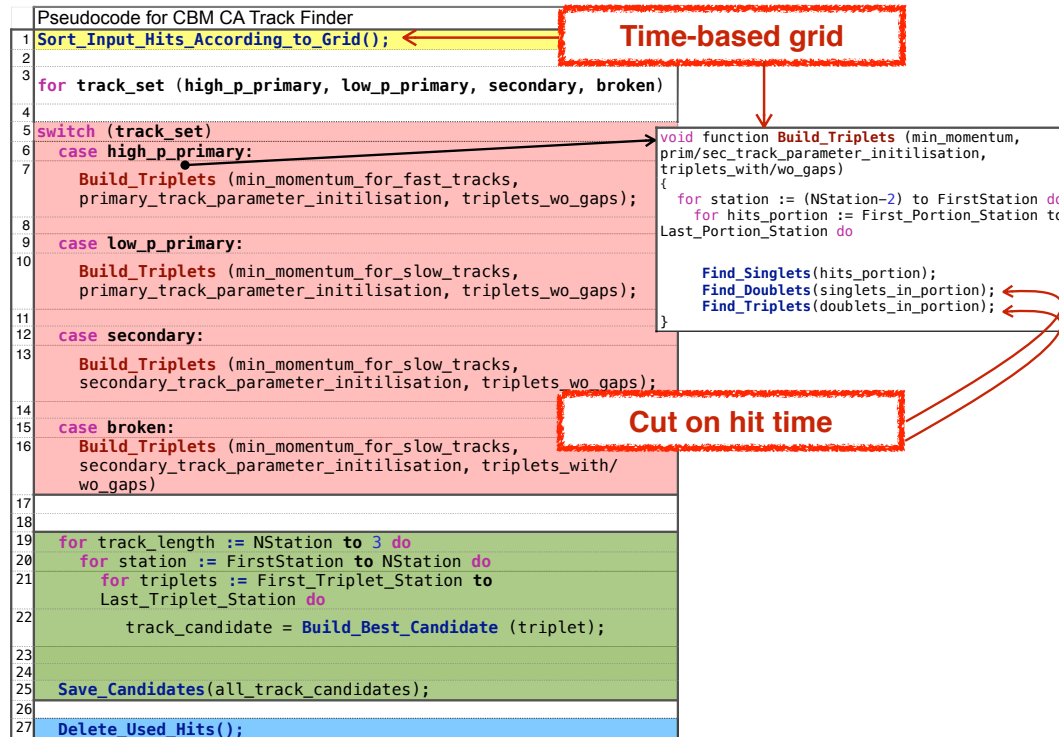

Switching to 4D tracking formally implies that the time coordinate should be added to the state vector of a track:

$$(x, y, t_x, t_y, q/p) \rightarrow (x, y, t_x, t_y, q/p, t). \quad (7.1)$$

and all the operations with a state vector (e.g. propagation, fitting) should involve time coordinates to the same extent as it does spacial coordinates.

The full implementation of this approach will be added after taking into account TOF detector time measurement, since it is several orders of magnitude more precise and should drastically improve the time coordinate resolution. For the studies involving STS detector alone, the time is included into the track parameters, although the propagation and fitting is done, taking into account only the spacial coordinates.

The question of how the hit time measurement can be used in the CA track finder has a straightforward answer. Since the triplets are to be built of three hits potentially produced by the same particle these hits should be correlated not

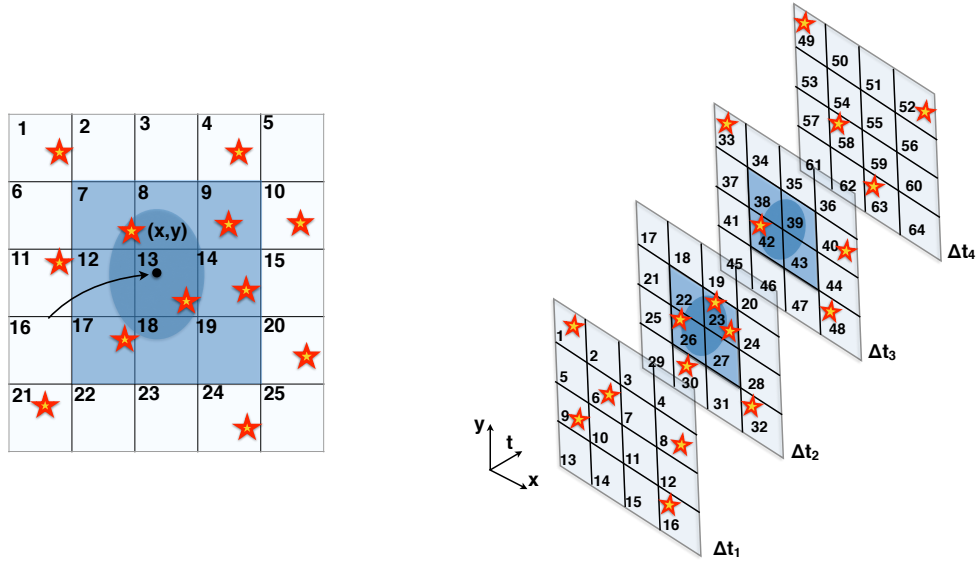

**Figure 7.3:** The pseudocode scheme for the parallel time-based CA track finder algorithm. In the time-based version the grid structure was modified to take into account time information. Also, the STS time measurement is used to reduce combinatorics in the triplet building stage.

only in space, but also in time. Neglecting the time of flight between stations, the hits belonging to the same track should coincide in time measurement within the detector time precision.

This requirement can be easily checked and fulfilled by applying a time cut on constructed doublets and triplets. All the combinations of hits, whose time measurements differ from each other more than the expected time of flight plus STS time precision should be rejected.

Since the neighboring triplets are defined as the ones sharing two hits in common, there is no need to change the later stages of combining triplets into tracks and apply additional time cuts. The time requirement will be automatically fulfilled due to the chosen triplet neighbor definition.

The modified scheme of the algorithm can be explained with the help of a pseudocode scheme (Fig. 7.3). The time requirement is checked inside `Find_Doublets` and `Find.Triplets` functions. The time difference between neighboring hits

**Figure 7.4:** The grid structure for one STS station to provide the fast access towards the hit measurements in the area of track extrapolation in the case of event-based analysis (left side) and the case of time-base tracking (right side).

should not be greater than three  $\sigma$ -values of the STS detector time resolution of 5 ns. It is a justified assumption, since the time of flight between the consecutive detector planes is negligible in comparison to the detector time precision.

Despite the fact that the described modification turns the CA track finder implementation into a 4D tracking algorithm, bringing the desired efficiency, it still is not sufficient for the CBM experiment. In the case of CBM not only performance, but also the speed of the algorithm is crucial. As it was shown, the most time-consuming part of the algorithm is the triplet building stage. Thus, providing the fast access towards the hit measurements in a certain spacial area while building triplets is crucial.

In order to achieve the speed comparable with the event-by-event analysis, a special grid data structure was introduced. In case of event-based analysis, all the hits on a certain station were sorted and stored according to their spacial ( $x_i$ ,  $y_i$ ) coordinates in the structure (Fig. 7.4, left side). In case of time-based tracking this approach requires taking into account not only spacial coordinates, but also the STS time measurement of a hit ( $x_i$ ,  $y_i$ ,  $t$ ) (Fig. 7.4, right side), turning the data structure from a 2D flat grid into a 3D scheme.

**Figure 7.5:** The speed-up factor due to parallelisation for different steps and the full 4D CA track finder algorithm on Intel Xeon E7-4860 CPU with 10 physical cores and hyper-threading in the case of reconstruction of a time-slice of 100 minimum bias Au+Au events at 25 AGeV.

Otherwise the number of random combinations to be considered by the track finder will grow exponentially for the case of time-slice-based reconstruction. Already at the stage of constructing doublets the CA track finder will have to consider  $N^2$  times more combinations, where  $N$  is the number of collisions in a time-slice, most of which will be rejected by the time cut. Thus, it is obvious that the grid data structure needs to be changed accordingly in order to keep a constant time to process a physical event in the traditional event-by-event analysis and the time-slice-based reconstruction.

The extrapolation of the 3D grid approach to the 4D version of the track finder has added one more dimension to this scheme — time. In this case all the hit measurements of a certain station of one time-slice are stored in several spacial grid structures as discussed above. Each grid time layer corresponds to a certain time interval in the ideal case representing one collision.

`L1HitArea` object was changed accordingly: instead of processing one layer of grid structure, in the 4D grid version algorithm needs to process several of them, taking into account detector time precision and extrapolation errors.

In the updated 4D grid version, the track finder instead of going through the whole list of hits in a time-slice, which corresponds to a certain spacial area, will have to address several layers of the grid structure corresponding to a certain time interval of interest. In this case the time to construct a triplet within a time-slice is comparable with the time to construct triplet in the case of event-by-event analysis.

Certainly, the time measurement has a strong influence on the algorithm performance and speed, which will be discussed in the next section. As for the scalability of the algorithm on the Intel Xeon E7-4860 CPU after taking into account STS hit time measurement, the resulting speed-up factor for the full time-based algorithm within one CPU is 10.1 (Fig. 7.5).

Efficiency, %	3D	3+1 D	4D
All tracks	83.8	80.4	83
Primary high- $p$	96.1	94.3	92.8
Primary low- $p$	79.8	76.2	83.1
Secondary high- $p$	76.6	65.1	73.2

**Table 7.1:** Track reconstruction performance for 100 minimum bias Au+Au collisions at 25 AGeV in the case of the event-by-event analysis (3D), grouped on a hit level with no time information (3 + 1D) and the time-based reconstruction (4D). No track merging and extending procedures are included.

### 7.3 Four-dimensional track finder performance

After the algorithm was modified, the time-based track finder version was tested to reproduce the results of the event-by-event analysis. In Tab. 7.1 one can find

the efficiencies of the 4D CA track finder for different track sets in comparison with the event-by-event analysis and the reconstruction in high track multiplicity environment. One can see that the results of the 4D CA track finder are comparable to the ones of the event-by-event reconstruction with the 3D CA track finder.

Also, the 4D CA track finder can nearly reproduce the speed of the 3D CA track finder, due to optimised data access structure. The slight difference in the performance of the event-by-event analysis and the time-slices-based reconstruction is due to the difference in the cut parameters optimization for low momenta tracks.

Efficiency, %	3D	4D
All tracks	90.6	92.2
Primary high- $p$	97.6	97.9
Primary low- $p$	93.2	93.5

Time/event/core	11.7 ms	13.6 ms

**Table 7.2:** Track reconstruction performance for Au+Au minimum bias event at 25 AGeV with the event-by-event analysis from the CBMROOT as well as for the time-slices-wise reconstruction assuming the 10 MHz interaction rate [105]. Track merging and extending procedures are included.

After the algorithm parameters were unified and adjusted to the ones used in the CBMROOT framework [106] version for the event-based analysis, both algorithms have showed the same performance. The resulting performance and the speed for the reconstruction of Au+Au minimum bias event at 25 AGeV with event-by-event analysis from the CBMROOT as well as for time-slices-wise reconstruction assuming 10 MHz interaction rate are presented in Tab. 7.2.

This test was done in order to check the correctness of the reconstruction

**Figure 7.6:** Residual and pull distributions for the tracks reconstructed by the 4D track finder, calculated at the point of the first hit position in the CBM STS detector. The width of the pull distributions is close to one, that indicates the correctness of the fit.

procedure and prove that the modifications have not affected the efficiency and quality available for the case of event-based analysis.

As one can see including the time measurement and optimization of the 3D CA algorithm towards the 4D reconstruction have made it possible to achieve the speed comparable to the case of the event-by-event analysis. Moreover, the track reconstruction efficiency has improved after taking into account the STS time measurement, while comparing it to the event-based performance. The effect is present even for the extreme case of 10 MHz interaction rate.

It can be explained by the presence of low momentum particles, which create random combinations of hits in case of the event-based approach. These random combinations can be rejected in the case of time-slices due to the hit time measurement cut, thus further improving the performance.

The study of the CA track finder algorithm stability in a high track density environment has shown that the speed of the algorithm was decreasing as a second order polynomial with respect to the track density. The comparison of

this result with the results obtained for the modified time-based version shows that 4D algorithm is able to reproduce the speed and efficiency of the event-by-event analysis. This corresponds to the desired linear growth of time with respect to the number of events processed.

The track parameters as well as residual distributions were calculated at the first hit position of each reconstructed track. The distributions for the  $x$ ,  $t_x$ ,  $y$ ,  $t_y$  and  $q/p$  parameters together with their Gaussian fits are shown in Figure 7.6.

All distributions are not biased with pull widths close to 1.0 indicating correctness of the fitting procedure. The slight deviations from 1.0 are caused by several assumptions made in the fitting procedure, mainly in the part of the detector material treatment. The  $q/p$  pull is the widest being the most sensitive to these simplifications, since it is an indirect measurement, which requires at least three hit measurements. The slightly narrow pull distributions for  $x$  and  $y$  parameters are due to the underestimated hit errors in the current CBMROOT implementation.

The algorithm was included into the CBMROOT framework. The simulation of detector response in this case provides a time measurement, taking into account the anticipated behavior of the detector, e.g. time-based clustering algorithm in the STS detector. Cluster finding is the first step of the STS hit reconstruction. A cluster is a group of adjacent hit strips in a sensor with a common time stamp. In an event-based scenario, fired strips are combined into a cluster only by their location and charges. However, a time-slice includes many events, that are distributed in time.

This, for instance, mean that a fake hit in this approach will be produced not only for strips accidentally fired simultaneously within a single event, but within a certain time interval. Thus, it puts the track finder to a more challenging condition, due to the increased fake hit rate.

The performance for the algorithm included into the CBMROOT framework for the case of reconstruction of time-slices, created of Au+Au minimum bias events at 10 AGeV, is presented in the last column of Tab. 7.3. It is comparable to the case of event-based analysis. The slightly higher clone level may be explained by the time measurement cut, which may be too strict for this case and may require additional optimization.

**Figure 7.7:** Residual and pull distributions for the tracks reconstructed with the 4D track finder included into the CBMROOT framework, calculated at the point of the first hit position. The width of the pull distributions is close to one, that indicates the correctness of the fit.

The distributions of residuals and pulls for all track parameters in the CBM experiment together with their Gaussian fits are shown in Fig. 7.7. All distributions are not biased with pull widths close to 1.0 similarly to the results of standalone algorithm.

## 7.4 Event building

As a rule, the track reconstruction is followed by the analysis of physical events in the conventional data reconstruction chain. However, since resolving different events for further physics analysis is a non-trivial task in the case of the CBM experiment, the standard reconstruction routine should include event building, the process of defining exact borders of events within a time-slice and grouping tracks into event-corresponding clusters. For this task an efficient time-based

Efficiency, %	E-by-E	10 <sup>5</sup> Hz	10 <sup>6</sup> Hz	10 <sup>7</sup> Hz	CBMROOT 10 <sup>7</sup> Hz
All tracks	92.1	92.6	92.6	92.2	91.3
Primary high- $p$	97.9	98.2	98.2	97.9	99.1
Primary low- $p$	93.6	94.1	94.1	93.5	93.6
Secondary high- $p$	92.0	92.7	92.7	92.0	88.9
Secondary low- $p$	65.7	66.7	66.6	65.9	56.8
Clone level	2.8	0.3	0.3	3.1	3.7
Ghost level	4.9	3.5	3.5	4.2	1.9
MC tracks found	145	146	146	145	88
Time, ms/ev	11.7	12.0	11.9	13.6	17.3

**Table 7.3:** Track reconstruction performance for 100 minimum bias Au+Au collisions at 25 AGeV in the case of event-by-event reconstruction, the time-slice-based reconstruction at 0.1 MHz, 1 MHz and 10 MHz interaction rates. The performance for the algorithm included into the CBMROOT framework is shown for Au+Au minimum bias time-slices at 10 AGeV and the 10 MHz interaction rate.

tracking algorithm is essential.

In order to perform further analysis, after the 4D track finder reconstruction is finished, to each track a time measurement is assigned. The track time measurement is calculated based on the STS time measurements of all hits contributing to the track. It is defined as an average of hit time measurements, extrapolated to the position of the reconstructed collision vertex. While extrapolating the time measurements, the tracks are assumed to be produced by particles flying along a trajectory close to the straight line with a speed close to the speed of light.

The initial distribution of hit measurements representing the complexity of defining event borders in a time-slice at an interaction rate of 10<sup>7</sup> Hz is shown in the upper part of Fig. 7.8. One can clearly see that at such extreme interaction rate there are no isolated events.

At the next step the algorithm needs to group reconstructed tracks in time into clusters of tracks belonging to the same collision, identifying thus physical events. Based on the developed 4D CA track finder algorithm, the first version of a simplified event building algorithm was implemented [107, 108].

The task is done by a histogramming: reconstructed track time measurements from a time-slice were used to fill a histogram with a bin width of 1 ns, which

**Figure 7.8:** A part of a time-slice with 100 minimum bias Au+Au events at 25 AGeV. The upper picture: with a blue color the distribution of hit time measurements in a time-slice is shown. The picture below: with a light blue color the initial distribution of hit measurements is shown (the same as in the upper picture), on the top of that reconstructed track time clusters are shown with different colors.

corresponds to the reconstructed track time resolution. An event was built out of the tracks from the consecutive non-empty bins in the histogram with an allowed gap not wider than 4 empty bins in a row. The width of an empty bin gap is a parameter of the method, which can be adjusted.

The resulting time distribution of track clusters is shown in the lower part of Fig. 7.8 on the background of initial hit measurements distribution. The reconstructed track clusters clearly represent groups, corresponding to the collisions, which tracks originate from. Even in the area of the severe initial event overlap on a hit measurement level (Fig. 7.9) the time-based CA track finder allows

Built event types	% of all events
Single events	83 %
Events in clusters	17 %
Splitted events	0 %

**Table 7.4:** The results of the event building procedure.

**Figure 7.9:** The event building: the reconstructed track groups are well resolved on the blue background of the initial collisions overlapped on a hit level.

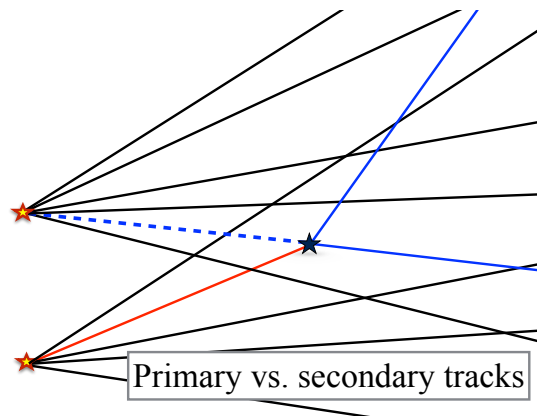

resolving tracks from different collisions in time.

The summarized results of event building procedure are shown in Table 7.4. One can see, that 83% of events were reconstructed without any event merging, 17% of events were reconstructed in merged double event clusters. Absence of event splitting was achieved.

The presence of event merging shows that STS time measurement information alone is not enough to resolve all events from each other on a track level at the extreme interaction rate of 10 MHz and there is still 17% to be resolved later with the use of event topology and multi-vertex analysis.

Here it is important to mention that all the discussed results were obtained for the STS detector alone, whose time resolution was assumed to be 5 ns. In future it is planned to include in the study the TOF detector, whose expected time resolution is of the order of 80 ps, which is two orders of magnitude better. The TOF detector measurement is expected to improve the experiment ability to resolve data from different collisions. However, there is always a certain probability that two events will overlap in time within a given detector time resolution.

In order to deal with such situations, additional information on the collision topology should be employed. In this case the reconstructed event topology can be used in the search for several independent primary vertexes. In the case when more than one vertex are identified, the primary tracks can be easily associated

**Figure 7.10:** The multi-vertex analysis: primary tracks should be associated with the vertex, which they originate from, secondary tracks are the subject of additional studies.

with a corresponding primary vertex, while the secondary tracks will contribute to the source of additional background for the physics analysis (Fig. 7.10). The extent of influence for the additional background can be investigated and estimated in a dedicated study.

# Chapter 8

## Summary and conclusions

The CBM (Compressed Baryonic Matter) experiment at the upcoming FAIR accelerator (GSI, Darmstadt, Germany) aims to explore the phase diagram of strongly interacting matter at the highest net baryon densities by investigating nuclear collisions from 2 to 45  $A$ GeV. One of the most promising observables carrying information on the early stage of collision are measurements of rare probes (e.g. charmonium), which require unprecedented statistics for this energy range and, thus, collision rates of up to 10 MHz. Taking into account multiplicity of charged particles in a heavy-ion collision, one should expect a data flow rate of 1 TB/s. Such a huge data rate makes it mandatory to select interesting events online with a reduction factor of about two orders of magnitude in order to meet the data recording rate of 10 GB/s.

CBM will operate on a continuous beam without bunch structure. As a result, collisions may overlap in time, making the traditional event-based approach not applicable. That requires the full online event reconstruction and selection not only in space, but also in time, the so-called 4D event building and selection. The problem is to be solved online on a dedicated many-core CPU/GPU computer farm by the First Level Event Selection package. This requires the package to be fast, precise and suitable for online data processing in order to use the full potential of modern many-core computer architectures.

For the most time-consuming part of the reconstruction procedure the Cellular Automaton track finder is used. The efficiency of the algorithm proved to be stable with respect to track multiplicity up to the extreme case of reconstruct-

tion of 100 minimum bias events at once without usage of the time information. The reconstruction time dependence on the track multiplicity in these conditions behaves as a second order polynomial.

The event-based CA track finder was adapted for time-slice-based 4D track reconstruction, which is a requirement in case of CBM for the event building. The 4D CA track finder is able to reproduce the performance and the speed of the event-based CA track finder. The algorithm was included into the CBMROOT framework.

The 4D CA track finder is both vectorized (using SIMD instructions) and parallelized (between CPU cores). The algorithm shows strong scalability on many-core systems. The speed-up factor of 10.1 was achieved on a CPU with 10 hyper-threaded physical cores.

The 4D event building was implemented in the standalone FLES package for the CBM experiment. It allows resolving the major part of overlapping on a hit level events and group tracks into event-corresponding clusters without event splitting. About 17 % of events are merged and cannot be separated using only the time information at an interaction rate of 10 MHz. Resolving them is a task for further multi-vertex analysis as well as for a study with the included TOF (Time-Of-Flight) detector.

The 4D CA track finder algorithm is ready for time-slice-based reconstruction for the CBM experiment.

7.1	Track reconstruction performance for 100 minimum bias Au+Au collisions at 25 AGeV in the case of the event-by-event analysis (3D), grouped on a hit level with no time information (3 + 1D) and the time-based reconstruction (4D). No track merging and extending procedures are included. . . . .	140
7.2	Track reconstruction performance for Au+Au minimum bias event at 25 AGeV with the event-by-event analysis from the CBMROOT as well as for the time-slices-wise reconstruction assuming the 10 MHz interaction rate [105]. Track merging and extending procedures are included. . . . .	141
7.3	Track reconstruction performance for 100 minimum bias Au+Au collisions at 25 AGeV in the case of event-by-event reconstruction, the time-slice-based reconstruction at 0.1 MHz, 1 MHz and 10 MHz interaction rates. The performance for the algorithm included into the CBMROOT framework is shown for Au+Au minimum bias time-slices at 10 AGeV and the 10 MHz interaction rate. . . . .	145

7.4	The results of the event building procedure. . . . .	147
1	Die Spurrekonstruktion Performanz des CBM CA-Spurfinders für verschiedene Sätze von Spuren in den Minimum-Bias und zentralen Ereignisse bei 25 AGeV. 175	
2	Effizienz (in %) der Spurrekonstruktion für 100 Minimum-Bias Au+Au Kollisionen bei 25 AGeV bei ereignisweiser Rekonstruktion als auch bei zeitschnittbasierter Rekonstruktion bei 0,1 MHz, 1 MHz und 10 MHz Kollisionsraten. Die Effizienz für den Algorithmus, der im CBMROOT-Framework enthalten ist, wird für Au+Au Minimum-Bias-Zeitschnitten bei 10 AGeV und 10 MHz Kollisionsrate gezeigt. . . . .	180

# Zusammenfassung

## Motivation

In den letzten Jahrzehnten sind weltweit große experimentelle und theoretische Anstrengungen unternommen worden, um die Eigenschaften von Kernmaterie unter extremen Bedingungen zu erforschen. Experimente mit hochenergetischen Schwerionen bieten die einzigartige Gelegenheit, heiße und dichte Kernmaterie im Labor zu erzeugen und experimentell zu untersuchen. Ziel der Experimente ist es, die Struktur und die Eigenschaften stark wechselwirkender Materie, die den Gesetzen der Quanten-Chromo-Dynamik (QCD) unterliegt, zu erforschen, und das QCD Phasendiagramm zu untersuchen. In Schwerionenstößen wird, je nach Kollisionsenergie, entweder sehr heiße Materie erzeugt, ähnlich der im frühen Universum wenige Mikrosekunden nach dem Urknall, oder sehr komprimierte Materie, wie man sie im Zentrum von Neutronensternen vermutet.

Das Compressed Baryonic Matter (CBM) Experiment an der zukünftigen Facility for Antiproton and Ion Research (FAIR) in Darmstadt wird eine einzigartige Rolle bei der Untersuchung des QCD Phasendiagramms bei hohen Materiedichten spielen, weil es darauf ausgelegt ist, Schwerionenstöße mit bisher beispiellos hohen Reaktionsraten zu messen. Hochratenexperimente sind erforderlich, um seltene diagnostische Proben, die auf die Eigenschaften dichter Kernmaterie sensitiv sind, mit hoher Präzision und Statistik zu messen, wie zum Beispiel mehrfach-seltene Hyperonen, Leptonenpaare und Teilchen, die Charm-Quarks enthalten. Die Zerfallstopologien dieser Teilchen sind komplex, sodass kein Hardware-Trigger generiert werden kann, um die Daten zu selektieren. Daher wurde für das CBM-Experiment ein neuartiges Datenauslese- und Datenaufnahmekonzept entwickelt, das auf selbstgetriggertem (freilaufendem) Front-End-

Elektronik basiert. In diesem Fall muss die Datenanalyse erfolgen, was vierdimensionale Rekonstruktions-Algorithmen erfordert. Diese sehr schnellen Algorithmen zur online Ereignisrekonstruktion und Selektion in Echtzeit müssen an die Architektur von Hochleistungsrechnern angepasst sein.

Die Central Processing Units (CPUs) mit Dutzenden Cores und Graphic Processing Units (GPUs) mit tausenden Recheneinheiten sind die Hauptkomponenten eines modernen Hochleistungsrechners. Diese Rechnertechnologien erlauben die Berechnung mehrerer Aufgaben parallel und simultan. Um diese Architekturen effizient zu nutzen, müssen Parallelrechnungen angewendet werden. Es ist zu erwarten, dass die Parallelisierung von Rechenleistung in Zukunft weiter fortschreiten wird, mit mehr Cores pro CPU und mehr Elementen pro Vektorregister. Daher ist es von entscheidender Bedeutung, das volle Potential dieser komplexen Technologie auszunutzen. Zu diesem Zweck müssen Programme so entworfen werden, dass die Geschwindigkeit der Anwendungen mit der Zahl der parallelen Elemente in einem heterogenen System skaliert. Im Idealfall sollten die Algorithmen eine starke lineare Skalierbarkeit auf parallelen Architekturen aufweisen.

## **Rekonstruktion von Teilchenspuren**

Die Analyse von Reaktionen in der Hochenergiephysik besteht in der möglichst genauen Bestimmung der kinetischen Parameter der Teilchen. Geladene Teilchen, die in der Reaktion erzeugt werden, ionisieren das Detektormaterial, und die dadurch generierten Signale ermöglichen so eine Reihe von Positionsmessungen entlang der Trajektorie. Die Topologie der Reaktion wird bestimmt durch die Rekonstruktion der Spuren geladener Teilchen. Die Aufgabe der Spurrekonstruktion besteht allgemein aus zwei Teilen: Spurfindung und Spurbestimmung. Die Spurfindung stellt ein Problem der Mustererkennung dar, wobei ein kompletter Satz von Detektorsignalen aufgelöst werden muss in Signale, die nur von einem einzigen Teilchen erzeugt wurden. Die Spurbestimmung erfolgt nach der Spurfindung und beinhaltet die Abschätzung von Spurparametern und ihren Fehlern, um kinematische Eigenschaften von Teilchen zu bestimmen.

Derzeit finden eine Vielzahl von Spurfindungsmethoden Verwendung, die in

**Abbildung 1:** Eine Illustration der Komplexität der Spurfindung (von links nach rechts): die Spuren von einer simulierten Au+Au Kollision bei 25 AGeV; die Detektortreffer im STS als Eingangsinformation für den CA-Spurfinder; die mit dem CA-Spurfinder rekonstruierte Spuren.

der Vorgehensweise voneinander stark abweichen, was einen direkten Vergleich unmöglich macht.

Das Finden der Trajektorien geladener Teilchen bei hohen Spurdichten, wie sie in Schwerionenkollisionen vorkommen, wird in der Regel als der schwierigste und zeitaufwändigste Schritt des Rekonstruktionsverfahrens angesehen (Abbildung 1). Grund dafür ist üblicherweise ein sehr spezifisches Problem der Kombinatorik, die mit der Spurmultiplicität rasch wächst, wenn Positionsmessungen zusammengefasst werden in Gegenwart von Untergrundsignalen.

Der auf dem zellulären Automaten (Cellular Automaton, CA) basierende Spurfinder stellt eine solide Lösung der kombinatorischen Suchoptimierung dar. Diese Methode profitiert von einer drastischen Unterdrückung der kombinatorischen Möglichkeiten durch die Einführung von kurzen Teilspuren in einem frühen Stadium vor der Hauptsuche.

Darüber hinaus erfolgt diese Methode in Bezug auf Datenverarbeitung im wesentlichen lokal und kann so auf modernen Many-Core-Architekturen (CPU/GPU) parallel laufen. Die Eigenschaften der CA-Methode machen den Algorithmus zu einer geeigneten Lösung für die Spurrekonstruktion im Silicon Tracking System (STS), dem wichtigsten Spurdetektor des CBM-Experiments.

Um die Rekonstruktion im Falle einer hohen Spurdichte schnell und zuverlässig zu gestalten, erfolgt die Suche nach Spuren im STS in mehreren Iterationen: bei der ersten Iteration sucht der Spurfinder lediglich nach primären hochenergetischen Spuren, bei der zweiten nach primären niedrigenergetischen Spuren und in der letzten nach sekundären Spuren. Nach jeder Iteration werden alle Treffer von

rekonstruierten Spuren als benutzt gekennzeichnet und im weiteren nicht mehr berücksichtigt, wobei die Kombinatorik bedeutend reduziert wird.

Der Kalman-Filter wird für Bestimmung von Spuren verwendet, die in den Spurdetektoren rekonstruiert wurden, um Spurparameter und ihre Fehler abzuschätzen. Der Algorithmus arbeitet in einfacher Genauigkeit stabil und ist vollständig vektorisiert. Er wird auch angewandt, um die Parameter teilweise rekonstruierter Spuren innerhalb des CA-Spurfinders zu bestimmen, während er nach Positionsmessungen in der nächsten Detektorstation sucht.

Für Auswertungszwecke wird eine rekonstruierte Spur einem simulierten Teilchen zugeordnet, wenn mindestens 70% ihrer Treffer von diesem Teilchen verursacht wurden. Ein simuliertes Teilchen wird als gefunden erachtet, wenn es mindestens einer rekonstruierten Spur zugeordnet werden kann. Wenn ein Teilchen öfter als einmal zugeordnet wird, werden sämtliche zusätzlich rekonstruierten Spuren als Klone betrachtet. Eine "Geisterspur" bezeichnet eine rekonstruierte Spur, die nicht zu einem erzeugten Teilchen nach dem o.g. 70%-Prinzip zugeordnet werden kann.

Die Effizienz der Spurrekonstruktion für verschiedene Spurklassen sowie die Anteile von Klon- und Geisterspuren werden in Tabelle 1 für Gold-Gold-Kollisionen bei 25 AGeV, die mit dem UrQMD-Modell simuliert wurden, gezeigt.

Die Mehrzahl der Signalspuren (Zerfallsprodukte von D-Mesonen, Charmonium, leichte Vektormesonen) sind Teilchen mit einem Impuls von mehr als 1 GeV/c und haben ihren Ursprung in unmittelbarer Nähe des Kollisionsspunkts. Ihre Rekonstruktionseffizienz ist daher ähnlich wie die Effizienz der Hochimpulsprimärspuren, die 97,1% beträgt. Die Hochimpulssekundärteilchen (z. B. Tochterteilchen von  $K_s^0$ ,  $\Lambda$ ,  $\Xi$  und  $\Omega$ ) entstehen weit entfernt vom primären Kollisionsspunkt, so dass ihre Rekonstruktionseffizienz unter 81,2% liegt.

Signifikante Mehrfachstreuung von Niedrigimpulsspuren im Material des Detektorsystems und große Krümmung ihrer Bahnen lässt die Erfolgsrate einer Rekonstruktion bei Primärspuren auf 90,4% und bei Sekundärspuren auf 51,1% sinken.

Die Gesamteffizienz für alle Spuren beträgt 88,5% mit einem großen Anteil von sekundären Niedrigimpulsspuren. Die Anteile von Klon- und Geisterspuren betragen 0,2% bzw. 0,7%.

**Tabelle 1:** Die Spurrekonstruktion Performanz des CBM CA-Spurfinders für verschiedene Sätze von Spuren in den Minimum-Bias und zentralen Ereignisse bei 25 AGeV.

**Abbildung 2:** Die Effizienz der Spurrekonstruktion und Geisterspur-Rate in verschiedenen Spurguppen im Vergleich zu Spur-Multiplizität.

## Spurfindung bei hoher Spurmultiplicität

In modernen Hochenergie-Schwerionenexperimenten sind die Spurdichten pro Reaktion und die Reaktionsrate so hoch, dass eine erfolgreiche Messung wesentlich von der Effizienz der Rekonstruktionsmethoden abhängen wird. Die Kollisionsraten in den gegenwärtigen Experimenten haben ein solches Ausmaß erreicht, dass die verfügbare Zeit zur Rekonstruktion überlappender Signale äußerst knapp ist. Signalüberlapp tritt auf, wenn mehrere Ereignisse so dicht nacheinander auftreten, dass ein Teilchendetektor sie alle gleichzeitig verarbeiten muss. Der Überlapp (pile-up) steigert die Komplexität der Spurrekonstruktion, weil die Spurmultiplicität sich dabei um Faktoren erhöht.

Dies bedeutet für die Spurrekonstruktion, dass mehrere Ereignisse mit einem komplexeren Muster in kürzerer Zeit berücksichtigt müssen. Dies steigert die Anforderung an die Geschwindigkeit und Leistungsfähigkeit des Rekonstruktion-Algorithmus. Intuitiv würde man erwarten, dass die Komplexität der Rekonstruktion der Anzahl der Spuren entspräche, was leider nicht der Fall ist. Die Spurfindung stellt vielmehr ein kombinatorisches Problem dar, das dem berühmten Problem des Handlungsreisenden ähnlich ist. Die Problematik gehört zur Klasse der NP-vollständigen (nichtdeterministischen Polynomialzeit) Pro-

bleme gemäß der Theorie der Rechenkomplexität. Somit ist es möglich, dass im schlimmsten Fall bei jedem Algorithmus das Problem superpolynomial (z. B. exponentiell) mit der Spurmultiplicität wächst.

Somit ist die erste Herausforderung für die Spurrekonstruktion im Falle einer erhöhten Multiplicität der exponentielle Anstieg der Rechenzeit pro Ereignis.

Eine hohe Trefferdichte im Detektor resultiert in einer hohen Kombinatorik in der Spurfindung und in einer Verlangsamung des Algorithmus. Darüber hinaus führt eine große Spurenmultiplicität zu einer hohen Detektorbelegung, dass eine erhöhte Anzahl von falsch rekonstruierten Spuren daraus resultiert. Ein guter Spurfinder ist robust gegen große Multiplicitätsschwankungen. Deshalb ist die Spurfinder-Stabilität besonders wichtig bei modernen HEP-Experimenten.

Da das CBM-Experiment bei extrem hohen Kollisionsraten betrieben wird, können sich verschiedene Kollisionen zeitlich überlappen, so dass die Möglichkeit, sie auf triviale Weise zu trennen, nicht besteht. Somit ergibt sich die Notwendigkeit, statt isolierter Ereignisse sogenannte Zeitschnitte, die Informationen aus einer Anzahl von Kollisionen enthalten, zu analysieren. Die Notwendigkeit, mit Zeitschnitten zu arbeiten statt mit Ereignissen, ist nicht nur aus physikalischen, sondern auch aus computertechnischen Gründen erforderlich. Nicht nur Minimum-Bias-Ereignisse, sondern auch zentrale Ereignisse erwiesen sich als nicht groß genug, um auf modernen Mehrkernarchitekturen parallel verarbeitet zu werden. In-Ereignis-Parallelität kann nicht implementiert werden, weil diese Ereignisse nicht über genügend Quellen der Parallelität verfügen, um mit vielen Kernen gleichzeitig rekonstruiert werden zu können.

Als erster Schritt auf dem Weg in Richtung Zeitschnitt-Rekonstruktion führen wir einen mit Minimum-Bias-Ereignissen gepackten Container ohne Zeitinformationen ein. Zur Erstellung einer solchen Gruppe kombinieren wir Raumkoordinaten von Treffern aus einer Zahl (von 1 bis 100) von Ereignissen (minimum-bias Au+Au bei 25 AGeV) und ignorieren solche Informationen wie Ereignisnummer oder Zeitmessungen. Dabei wird vorausgesetzt, dass die Raumkoordinaten der Treffer selbst in jedem einzelnen Ereignis aus den Rohdaten rekonstruiert wurden. Die Problematik der für Streifendetektoren typischen, kombinatorischen Falschtreffer wird also nur auf Ereignisebene, nicht in der Gesamtgruppe berücksichtigt.

Die Gruppe wurde von dem CA-Spurfinder als einzelnes Ereignis behandelt,

**Abbildung 3:** Die Zeit, die der CA-Spurfinder benötigt, um Gruppen von Minimum-Bias-Ereignissen ohne Zeitinformation zu rekonstruieren, als Funktion der Spuranzahl. Die Abhängigkeit wird mit einem Polynom zweiter Ordnung beschrieben.

**Abbildung 4:** Beschleunigungsfaktor aufgrund der Parallelisierung für verschiedene Schritte und den vollständigen Algorithmus auf Intel Xeon E7-4860 CPU mit zehn physischen Kernen und Hyper-Threading für den Fall von 100 zusammengefassten Minimum-Bias-Ereignissen.

und das Rekonstruktionsverfahren wurde ohne Änderungen durchgeführt. Wir haben die Effizienz der Spurrekonstruktion im Hinblick auf die Spurmultiplicität untersucht, wobei wir die Anzahl der Minimum-Bias-Ereignisse in der Gruppe variiert haben.

Abbildung 2 zeigt die Rekonstruktionseffizienz für verschiedene Spurklassen als Funktion der Spuranzahl im (aus mehreren Minimum-Bias-Kollisionen zusammengefassten) Ereignis. Primäre Hochimpulsspuren (RefPrim), die von besonderer physikalischer Bedeutung sind, werden mit einer Effizienz von etwa 96% rekonstruiert wurden. Dies variiert bei bis zu 100 kombinierten Ereignissen um weniger als 2%.

Bei der Berücksichtigung von Sekundärspuren (Refset) reduziert sich die Effizienz auf 93,7% und variiert bis zu 3% bei den zusammengefassten Extremfällen von 100 Minimum-Bias-Ereignissen. Die Effizienz bei Niedrigimpulsspuren beträgt 79,8% (ExtraPrim) und ändert sich innerhalb von 6% bei größter Spurmultiplicität. Der Anteil der Geisterspuren bleibt auf einem akzeptablen Niveau (weniger als 10%) bis zu den höchsten Spurmultiplicitäten. So erweist sich der CA-Spurfinder in Bezug auf Spurmultiplicitäten als stabil.

Jedoch nicht nur die Effizienz, sondern auch eine Geschwindigkeit des Rekonstruktionsalgorithmus ist für eine erfolgreiche Durchführung des CBM-Experiments entscheidend. Die Zeit, die ein CA-Spurfinder benötigt, um ein Gruppenereignis zu rekonstruieren, wurde als Funktion der Anzahl von Monte-Carlo-Spuren in einer Gruppe untersucht. Die Ergebnisse zeigen, daß die Abhängigkeit mit einem Polynom zweiter Ordnung angenähert werden kann (Abbildung 3). Dies ist ein vielversprechendes Ergebnis, insbesondere im Hinblick auf das exponentielle Wachstum der Kombinatorik bezüglich der Spurmultiplicität. Diese Abhängigkeit kann weiter verbessert und zu einer linearen Funktion gemacht werden, die nach der Einführung der Zeitmessung im Rekonstruktionsalgorithmus der Abhängigkeit der ereignisbasierten Analyse entspräche. So zeigen sowohl die Geschwindigkeit und Effizienz des CA-Spurfinders stabiles Verhalten bei hoher Spurmultiplicität.

## Paralleler CA-Spurfinder

Der CA-Spurfinder-Algorithmus wurde in Bezug auf Parallelität neu gestaltet und optimiert. Jeder Schritt des Algorithmus wurde in einem Super-Ereignis mit OpenMP- und Pthreads-Schnittstellen parallelisiert. In jedem Stadium werden die Quelle der Parallelität-Elemente gleichzeitig verarbeitet und in einer neuen Form mit einem höheren Konsolidierungsumfang gespeichert. Während der Initialisierungsphase werden alle Eingangstreffer bezüglich ihrer Koordinaten sortiert und in einem Raumgitter gespeichert. Eine gewisse Anzahl von Treffern (teilbar durch die Breite des SIMD-Vektor) wird zusammengefasst und aufgeteilt, um künftig verarbeitet zu werden. In der Aufbauphase von Triplets werden Trefferteile verarbeitet ohne Synchronisation zwischen Threads, woraus sich eine Reihe von Triplets ergibt. In der folgenden Phase der Spurkandidatenerstellung sind Triplets die Quelle der Parallelität.

Gleichzeitig stellt der Algorithmus für jedes Ausgangstriplet den bestmöglichen Spurkandidaten nach  $\chi^2$ -Wert und Länge auf. In dieser Phase arbeiten die Threads noch unabhängig. In der vorangegangenen Phase der Spurselektion mussten die Threads miteinander kommunizieren, um die Treffer zwischen den Spuren zu verteilen. In der Spurselektionstufe wurde die Synchronisation mit-

tels einer Tabelle des gemeinsamen Zugriffs implementiert. In der letzten Phase werden die verwendeten Treffer für die nächste Iteration entfernt. Hier repräsentieren die vorliegenden Treffer die Quelle der Parallelität, wie bei der Initialisierungsphase.

Die sich ergebenden Beschleunigungsfaktoren für die verschiedenen Phasen sowie für den gesamten Algorithmus innerhalb einer CPU (20 Hyper-Threading-Kerne) sind in Abbildung 4 dargestellt. Einige Schritte haben aufgrund geringer Thread-Synchronisation eine erhöhte Beschleunigung für eine höhere Anzahl von Kernen. Der Algorithmus zeigt eine lineare Skalierbarkeit. Aufgrund von Hyper-Threading kann man auf einer solchen CPU im Idealfall eine Beschleunigung um einen Faktor 13 erwarten. Der erreichte Beschleunigungsfaktor ist 10.1 für den gesamten Algorithmus auf einer CPU mit 10 physischen Kernen mit Hyper-Threading.

## 4D paralleler CA-Spurfinder

Da die Separierung unterschiedlicher physikalischer Ereignisse im CBM-Experiment keine triviale Aufgabe ist, musste der CA-Spurfinder so modifiziert werden, dass er auch Zeitinformationen berücksichtigen konnte. Der Algorithmus wurde so angepasst, dass er Eingangszeitschnitte erfasst, die Treffer von dem Spurdetektor enthält. Jeder Treffer enthält zwei Raumkoordinaten  $x$  und  $y$  in der Detektorebene  $z$  sowie die Zeitmessung  $t$ .

Die Zeitinformation wurde in dem CA-Spurfinder verwendet, um die Geschwindigkeit und die Effizienz des Algorithmus zu verbessern. Da die Triplets aus drei Treffern zusammengestellt werden sollen, die von ein und demselben Teilchen erzeugt wurden, sollten diese Treffer nicht nur räumlich sondern auch zeitlich korreliert sein. Vernachlässigt man die Flugzeit zwischen Detektorstationen, sollten die Treffer auf derselben Spur in der Zeitmessung innerhalb der Detektor-Zeitgenauigkeit übereinstimmen. Treffergruppen, deren Zeitmessungen sich um mehr als die erwartete Flugzeit inklusive Detektor-Zeitgenauigkeit voneinander unterscheiden, sollten verworfen werden.

Die sich ergebende Performanz und die Geschwindigkeit der ereignisweisen Analyse sowie für den 4D CA-Spurfinder für die Rekonstruktion von Zeitschnit-

ten, die aus 100 Au+Au Minimum-Bias-Ereignissen bei 25 AGeV erzeugt wurden, sind in Tabelle 2 dargestellt.

Deutlich zu beobachten ist, dass die Berücksichtigung der Zeit und die Optimierung des 3D-CA-Algorithmus in Richtung 4D-Rekonstruktion es ermöglichen, eine Geschwindigkeit zu erreichen, die vergleichbar mit der ereignisweisen Analyse ist. Zudem konnte die Effizienz der Spurrekonstruktion nach Berücksichtigung der Spurdetektor-Zeitmessung verbessert werden, so dass sie der ereignisbasierten Analyse entspricht. Der Effekt ist auch für den Extremfall von 10 MHz Kollisionsrate sichtbar. Das kann durch die langsamen Teilchen erklärt werden, die im Falle von einem ereignisbasierten Ansatz zufällige Kombinationen von Treffern erzeugen. Diese zufälligen Kombinationen können im Fall von Zeitschnitten durch Schnitte der Trefferzeitmessung verworfen werden, wodurch die Leistung verbessert wird.

Track category	E-by-E	$10^5$ Hz	$10^6$ Hz	$10^7$ Hz	CBMROOT

Time, ms/ev	11.7	11.97	11.92	13.60	17.30

**Tabelle 2:** Effizienz (in %) der Spurrekonstruktion für 100 Minimum-Bias Au+Au Kollisionen bei 25 AGeV bei ereignisweiser Rekonstruktion als auch bei zeitschnittbasierter Rekonstruktion bei 0,1 MHz, 1 MHz und 10 MHz Kollisionsraten. Die Effizienz für den Algorithmus, der im CBMROOT-Framework enthalten ist, wird für Au+Au Minimum-Bias-Zeitschnitten bei 10 AGeV und 10 MHz Kollisionsrate gezeigt.

Der Algorithmus wurde im CBMROOT-Framework implementiert. Dies ermöglicht einen realistischen Input für den Spurfundungsalgorithmus, da nun auch die Rekonstruktion der Detektortreffer zeitbasiert erfolgt und somit die für Streifendetektoren typischen kombinatorischen Fehltreffer korrekt behandelt werden. Dies stellt für den Spurfinder eine weitere Herausforderung dar.

Die Effizienz des Algorithmus im CBMROOT-Framework im Falle der Rekonstruktion von Zeitschnitten, die aus Au+Au Minimum-Bias-Ereignissen bei 10 AGeV bestehen, ist in der letzten Spalte der Tabelle 2 dargestellt. Diese Effizienz ist mit der ereignisbasierten Analyse vergleichbar. Die etwas höhere Klonrate könnte durch den Zeitmessungsschnitt erklärt werden, der für diesen Fall zu streng sein kann und eine weitere Optimierung erforderlich machen könnte.

## Fazit

Das First-Level Event Selektion (FLES) Softwarepaket für das CBM-Experiment enthält alle Rekonstruktionsstufen: Spurfindung, Spuranpassung, Suche nach kurzlebigen Teilchen, Ereignisbildung und Ereignisselektion.

Für den zeitaufwendigsten Teil des Rekonstruktionsverfahrens wird der Zelluläre-Automat-Spurfinder verwendet. Der CA-Spurfinder ist vektorisiert und zwischen CPU-Kernen parallelisiert. Der ereignisbasierte Algorithmus wurde auf zeitschnittbasierte Rekonstruktion angepasst, was bei CBM für die Ereignisbildung erforderlich ist. Der 4D CA-Spurfinder ist in der Lage, eine Performanz und Geschwindigkeit vergleichbar mit der ereignisbasierten Analyse im Falle extremer Kollisionsraten von 10 MHz zu erzielen. Der Algorithmus ist im CBMROOT-Framework implementiert. Somit ist das FLES-Paket betriebsbereit und kann im CBM-Experiment bei der 4D-Rekonstruktion von Zeitschnitten eingesetzt werden.

# Acknowledgements

I would like to thank all the people who contributed to and supported the work described in this thesis.

First of all I would like to express my deep sense of gratitude to Prof. Dr. Ivan Kisel, whose expert knowledge in both science and technology combined with his endless enthusiasm in implementing fresh ideas was a constant source of inspiration to me. I feel very lucky for the opportunity to work with the supervisor, who always was so much interested in my work.

I express my sincere appreciation to Prof. Dr. Peter Senger for his constant guidance and particularly for the opportunity to perform my study within the CBM collaboration. It has been a wonderful experience to work within the collaboration. Also I would like to thank Prof. Dr. Victor Ivanov for his constant support during those years.

I am very grateful to Dr. Iouri Vassiliev for the valuable experience, he shared with me, and the time, he has devoted to my work. A special thanks goes to Dr. Irina Rostovtseva for her contribution to porting the developed algorithm into the CBMROOT framework and to Iaroslava Bezshyiko for her collaboration in developing the event building algorithm. Also I would like to give a special thank to Prof. Dr. Peter Senger, Dr. Volker Friese and Kristine Eschedor for their help in translating the work in German.

Many thanks to my current and former colleagues for their support and the great and positive work environment, particularly I want to thank Maksym Zyzak, Igor Kulakov and Olga Derenovskaya.

Finally, I want to thank to my family and friends for all they have been doing for me during those years.

# Valentina Akishina

## Personal Information

Date of Birth 29.06.1988  
Place of Birth Dubna, Moscow region, Russia  
Citizenship Russian

## Education

- 2011–today **PhD Student**, *Johann Wolfgang Goethe University*, Frankfurt am Main, Germany.  
Subject: Computer Science  
Thesis Title: 4D Event Reconstruction in the CBM Experiment  
Supervisor: Prof. Dr. Ivan Kisel
- 2009–2011 **Master Student**, *Lomonosov Moscow State University*, Moscow, Russia.  
Subject: Physics  
Specialization: Physics and Management in Scientific Research and High Technologies  
Thesis Title: Hyperons decay reconstruction in Compressed Baryonic Matter experiment  
Supervisors: Prof. Dr. Viktor Ivanov, Prof. Dr. Alexander Olshevsky  
Average Grade: 4.9/5
- 2005–2009 **Bachelor Student**, *Lomonosov Moscow State University*, Moscow, Russia.  
Subject: Physics  
Specialization: Low Temperature Physics  
Thesis Title: Magnetic properties of  $Ge_{1-x}Mn_xTe$  ferromagnetic semiconductors doped with gadolinium.  
Supervisor: Dr. Elena Zvereva  
Average Grade: 4.8/5
- 1995–2005 **Pupil**, *Secondary school #4*, Dubna, Moscow region, Russia.

## Employment

- 2015–today **Scientist**, *Frankfurt Institute for Advanced Studies*, Frankfurt am Main, Germany.  
Software development of reconstruction routines for the CBM experiment.
- 2010–today **Software engineer**, *Joint Institute for Nuclear Research*, Dubna, Russia.  
Software development of reconstruction routines for the CBM experiment.
- 06.2010–  
08.2010 **Intern**, *Allied Testing*, Moscow, Russia.  
Creating Quality Assurance proposals.
- 09.2008–  
08.2009 **Academic Programs Coordinator**, *Moscow State University Business School*, Moscow, Russia.  
Management of educational process for Master students.

## Scientific Schools

- 08.2010–09.2010 **GSI International Student Program**, *GSI Helmholtz Centre for Heavy Ion Research*, Darmstadt, Germany.  
Performed algorithm design and implementation (C++) for short-lived particle reconstruction in the CBM experiment.
- 08.2013 **CERN School of Computing**, Nicosia, Cyprus.

## Awards

- 2011 The best talk award of the International Symposium on Nuclear Electronics and Computing, Varna, Bulgaria.

## Computer skills

- Advanced C/C++, OpenMP, Vc Library, SIMD, POSIX Library  
Intermediate OpenCL, ITBB, Linux OS, L<sup>A</sup>T<sub>E</sub>X, ROOT  
Basic Pascal, Delphi

## Languages

- Native **Russian**  
Advanced **English, German**

## Teaching experience

- 09.2013–08.2015 **Practical Course**, *Johann Wolfgang Goethe University*, Frankfurt am Main, Germany.  
Title: Architecture of High-Performance Computers  
Level: Bachelor's and Master's degree
- 05.2014, **Lecture Course**, *FAIR-Russia Research Centre*, Moscow, Russia.  
02.2015 Title: Introduction into parallel computations on modern many-core computer architectures  
Level: Bachelor's, Master's and Doctorate degree
